THE
PHOTOGRAPHIC NEWS:

A WEEKLY RECORD

OF THE

PROGRESS OF PHOTOGRAPHY.

VOLUME VII.

EDITED BY G. WHARTON SIMPSON.

Nulla recordanti lux est ingrata.—MARTIAL.

LONDON:
PRINTED AND PUBLISHED BY THOMAS PIPER, 32, PATERNOSTER ROW.

1863.

THE HISTORY OF THE

ROYAL SOCIETY

LONDON:

THOMAS PIPER, PRINTER, 32, PATERNOSTER ROW.

P R E F A C E .

At the close of a volume we are permitted in a preface, or, to speak exactly, in a few after-words, to address our readers in a more direct and personal manner than on other occasions; in a manner somewhat similar to that of a Parliamentary representative, who meets his constituency at the close of a session, to review briefly his labours in the past, and renew his pledges for the future.

A glance through the pages of the volume we have just completed is suggestive of some very pleasant thoughts, as to the present position and future prospects of the Art of Photography. At no former period has its practice been so wide-spread, or its results so perfect; no former period has witnessed so much mental activity amongst its devotees, or so much commercial success amongst its professors generally; at no period has the PHOTOGRAPHIC NEWS been in communication with so large a circle of correspondents, or addressed such a numerous body of readers. Photographic journalism has indeed borne a singular position, in being so essentially a cause and a consequence of photographic progress. It is in no spirit of self-laudation, but simply for the purpose of mentioning a noteworthy fact, we make the remark, that in its literature Photography occupies a position unparalleled by any of the older Arts and Sciences. We know of no branch of Science or Art which has been or is so largely represented, which has its every fact and phase so completely recorded as Photography; of no exclusive or technical literature which has been so readily appreciated and freely encouraged as that of Photography.

We feel at once pride, pleasure, and encouragement in recognizing and contemplating these facts. We feel it a privilege to conduct a Journal for a circle of readers so enthusiastic and so appreciative. But we also feel a great responsibility. With each accession of readers—and during the year we have had many hundreds of accessions—we feel that responsibility is increased.

In the volume now in the hands of our readers, we have aimed primarily to present a perfect record of the year's Photographic Progress, in every quarter of the world: a record of scientific good results. Mr. Spiller's important discovery of free nitrate in the whites of finished glass plates; Cooper's experiments with resinized paper; the probable, to the diminished use of bromide, have discovered or confirmed; whatever artists have achieved; and, in our conviction, thus to be made clear; whatever new scope or fresh applications commercial photography has unfolded; whatever, in short, has conduced to the advancement of the Art, or the advantage of all classes of its adherents, we have endeavoured to chronicle with exactitude and fulness. Our second aim has been to aid the progress we have recorded, both by initiating improvements and giving impetus to those commenced by others. To this end we have been aided by a staff of contributors which has included some of the most able writers, skilled experimentalists, profound chemists, and accomplished photographers and artists who have been associated with the Art. To this end we have been aided by a highly intelligent and liberal circle of correspondents, to whose hints and suggestions our readers are largely indebted. And to this end our own energies, by constant experiment, observation, and research, have been entirely devoted.

We have the satisfaction of believing that we have not entirely failed in our aims. The encouraging communications we receive, and the rapidly increasing circle of readers we address, afford the best evidence that we have to no small extent succeeded in our efforts; and we here take occasion to offer our hearty and appreciative thanks to contributors and correspondents for their valued sympathy and aid.

So much for the past. For the future we need not many words: we prefer to be judged by merit rather than promise, by results rather than pledges. Wherein we have done well we will continue in well-doing. Wherein we can do better, we shall omit no opportunity or occasion of improvement which may be conducive to the interests or pleasure of our readers. The continued expansion of the art involves ever fresh demands upon its representative literature. We shall always endeavour to meet these demands. And whilst we shall hope to maintain for the PHOTOGRAPHIC NEWS the position of the guide and referee of the student; the registrar and text-book of the scientific experimenter; the counsellor and encourager of the artist and operator, we shall endeavour also to meet the requirements of the art in its rapidly widening applications as an important branch of Industry. In short, whatever relates to the advancement of the position of Photography as an art, a science, or a profession, we shall endeavour to uphold, and to worthily sustain the position of the exponent of Photography and representative of Photographers.

We conclude by wishing our readers a Merry Christmas and a Happy New Year.

THE PHOTOGRAPHIC NEWS.

Vol. VII. No. 226.—January 2, 1863.

PHOTOGRAPHY DURING THE PAST YEAR.

ANOTHER year of steady improvement has passed. No great or specific change in the general practice of the art, no great discovery or invention, has been added to the record. The year has, nevertheless, been one of decided activity and success.

At the commencement of the year the advent of the International Exhibition, and the position of photography therein, was a topic of all-absorbing interest. The Exhibition has come and gone, but its influence on photography has been comparatively unimportant. The relations between the two commenced with misunderstanding, and ended without satisfaction. It is true that in this Exhibition photography for the first time received definite recognition as a distinct and independent art; and it is true that it fully maintained, by the excellence of the various contributions and variety of its applications, its claim to such a position. In one point alone, so far as photography and photographers themselves are concerned, did the contributions come short of what might have been hoped and anticipated. We refer to the question of permanency. Many prints which were subjected to the influences of damp walls, and some which were not, faded very palpably, even whilst hanging in the Exhibition. That some prints, even when hung on the same walls, did not fade, proves, however, that none need have done so if the conditions of permanency were well understood and carefully observed.

Printing, without doubt, still continues to be the chief photographic difficulty. Processes for the production of negatives by different methods continue to improve, and little seems left to desire in this respect; but printing still progresses with slow and uncertain steps. It is true that, in skilful hands, despite the difficulties arising from imperfect knowledge and bad paper, very beautiful prints are produced. Still very little is understood of the *rationale* of the process, and very little certainty exists as to the permanency of the results. The attention which the subject has excited during the year it is probable may lead to some good results. Mr. Spiller's important discovery of the presence of free nitrate in the whites of finished prints, and Mr. Cooper's experiments with resinized paper, will tend, it is probable, to the diminished use of albumenized paper; and, in our conviction, thus to the removal of one of the causes of fading.

Setting aside the question of permanency, no branch of the art has been the subject of greater trouble and anxiety, even to skilled photographers, than the method of producing fine and brilliant prints; but the various researches and suggestions of the year have, we believe, contributed largely to reduce these difficulties. If all the causes of meanness or want of brilliancy are not well understood, at least the means of overcoming such difficulties are more familiar. The use of an ammonia-nitrate bath for albumenized paper has been found in many hands of immense value in this respect. Fuming the excited paper before printing is stated to have been found in the United States to give excellent results. The use of a bath of acetate of soda prior to toning has been found useful by many, and in others the perfect washing and soaking of the film of albumen, prior to immersion in the toning solution, has been found effectual in preventing meanness. In all cases the use of toning baths, mixed long enough to have attained maturity, and moderately slow toning, have been found of the utmost value. The efficiency

of various remedies indicates the fact that various causes for evil exist. A common opinion has prevailed to the effect that to the bad quality of the paper most of the causes might be traced. Mr. Sutton has proposed, by rendering the paper itself waterproof, to confine the image solely to the film of albumen on its surface. The same idea, in modified forms, has been proposed before, but not extensively carried out. From what we have seen of the results of the new suggestion, we hope much. But we shall see.

Associated with the question of permanent printing is the subject of photo-lithography, which has excited much interest during the year. For the purposes of reproduction of all subjects in which gradation is secured by artificial means, such as stippling or hatching, the processes of Col. James, Mr. Osborne, and others, seem to have attained perfection. The attention of the two gentlemen we have named has been almost solely confined to the reproduction of maps and similar subjects, and not to the securing of half tone. Recently Col. James has given some attention to that part of the question, and has favoured us with some examples which are full of promise. More recently we have been favoured with the examination of some specimens by the process of M. Asser, amongst which are by far the finest specimens of half tone we have seen.

The year has been prolific in modified dry processes. The tannin process has maintained its ground, or increased its popularity. Mr. England's modification, by the addition of honey, has proved very successful in many hands. Wet development and alkaline development have aided materially in shortening exposures with these plates, and, in some cases, in permitting the production of instantaneous pictures. Neither method of development is yet sufficiently well understood to give certainty to the processes, but the results of both are sufficient to indicate the fact that rapidity depends upon development as much or more than upon the preparation of the plate. The value of a full proportion of bromide in dry plates has been well-established on all hands. Mr. Sutton has proposed equal parts of bromine and iodine, as an imperative condition for rapid results. Mr. Keene has long prepared collodion for dry plates with such proportions, and, in his recently published interesting investigations in rapid dry photography, has had opportunity of fully confirming its value. Mr. Bartholomew has also added some valuable suggestions for dry plate photography, which have not been very extensively carried out, but have been nevertheless very successful. Messrs. Hislop, Ward, Window, and others, have offered valuable hints on the simplest of all dry processes—simply washed collodion, without preservation. In these hands plates thus prepared have been very successful. As to the simplicity and value of such a process, there cannot be two opinions.

We have reason to believe that, in portraiture at least, this year has been one of very great commercial success, especially amongst skilful photographers. We are glad to believe that a process of purgation has to some extent been going forward. What have been termed "Photographic Dens" have become more scarce, and able photographers more plentiful and successful. We have heard, with much satisfaction, of a large number of instances in which the number of portraits taken during this year have been more than double that of the preceding year.

In landscape photography we fear that there has been less activity. One of the most distinguished dry plate photographers informed us recently that he had not taken one

iv

andscape during the summer, so absorbing have been the demands of portraiture. Nevertheless, we hope that the forthcoming Exhibition will not be wanting in good examples of landscape photography.

Instantaneous photography has excited much attention during the year, and its conditions seem to be better understood as consisting in simplicity rather than complexity. Good chemicals, good lenses, and good light; bromodized collodion, and iron development, are generally known to be the main requisites. Breese's wondrous instantaneous transparencies have excited so much admiration, that he has been induced to appoint London agents for their sale; and his moonlight pictures, at one time regarded by many as a hoax, are now received as veritable results. Wilson, Blanchard, Kibble, Harman, and others, have all added their quota of instantaneous results during the year, whilst England has not been less usefully engaged in producing many thousands of charming souvenirs the art treasures in the Exhibition.

We have had the pleasure of chronicling various minor improvements during the year, which do not need specific mention here. Although there still remains much room for improvement, there has been unquestionable progress in the art aspects of photography. The appliances of photography have been improved, its applications extended, and increased activity generally been manifested. Photographic societies generally have not been progressing. The London societies have, it is true, increased in numbers, and some of the provincial societies have also been prosperous; but there has been a general declension on the whole, many of the societies having either died, or sunk into a torpor which resembles death.

One of the most important and satisfactory events of the year was the passing of the new Copyright Act, which gives to the photographer the sole right to reproduce his own pictures, and checks piracy by the prompt enforcement of penalties.

We confidently anticipate, in the coming year, continued progress, and hope for all our readers renewed and increased prosperity.

AMMONIA DEVELOPMENT.

THE recent experiments in ammonia development are likely to suggest many valuable theoretical conclusions, both regarding the nature of the process of development, and the operation of preservative preparations. It is clear, for instance, from recent experiment, that the use of the coating of tannin is not merely of a mechanical character. It is not simply a varnish helping to render the desiccated film permeable by aqueous solutions, as has been suggested by some authorities. If this were the case, a solution of ammonia would be sufficient to develop plates prepared by other methods. We recently tried the effect of ammonia on plates simply washed and dried without preservative. No perceptible result whatever followed; but on the addition of a little pyrogallie acid to the solution, an image rapidly appeared. The negative was not a satisfactory one, as, on intensifying, fog and irregular deposit ensued. We had not time then to repeat the experiment, only having a single plate at hand. A letter recently received from Mr. Leahy confirms this result, and adds the interesting fact that carbonate of soda answers the same purpose as ammonia. He writes as follows:—

SIR,—Since my former communication on the subject of developing by ammonia, I have been trying some experiments, with the view of finding out whether the development was due solely to the ammonia or to the tannin and ammonia combined. For this purpose I prepared plates by the ordinary tannin, the Fothergill and Sisson's (borax and gum) processes. The pictures taken on the plates, prepared by either the Fothergill or the borax and gum process, could not be developed by ammonia alone, but were rapidly brought out by a mixture of tannin and ammonia. The

proper proportions seem to be, from 10 to 15 drops of strong ammonia to an ounce of the ordinary 15-grain tannin solution. The plates prepared by the borax and gum process gave beautiful results, when treated with the foregoing mixture of tannin and ammonia. The pictures were of a reddish brown, and very sharp and vigorous, even before the application of the pyrogallie acid and silver; the principal use of the latter (with pictures developed by the above) being to intensify, almost all the details being visible before its application. I have also tried a solution of common soda for developing tannin plates, and with almost as much success as the ammonia. A solution of tannin, with the addition of a little soda, will develop either the Fothergill or the borax and gum prepared plates, but rather slowly. The foregoing modes of developing would, I should think, succeed with any of the dry processes, but I have tried them only with those mentioned.

The development seems to be owing to some decomposition of the tannin, as, in its absence, neither the ammonia or the soda produced any effect.—Your obedient servant,

THOMAS M. LEAHY.

Dublin, 16th December, 1862.

In a recent letter, Major Russell adds some interesting remarks, which we subjoin. He says:—

“With regard to the ammonia development, I have had no failures in the way of working I have described, except in a few of the earliest experiments, before I had found out the proper proportions of ammonia, and the necessity of thorough washing before intensifying with the ordinary developer. When these points were attended to, there has never been in my hands the slightest tendency to fogging or irregular action. My plates, I may observe, were all thoroughly freed from nitrate, sometimes by immersion in strong solution of salt, and always were soaked for hours in common water. I have found, by careful experiments, that the ordinary mode of development can be made to bring out an image after nearly as short an exposure as the ammonia and pyro, by using at first a very strong solution of pyro, with a mere trace of silver and acid; but in cases of short exposure, the ammonia treatment, besides economising the pyro, appears always to have its advantage in brightness and cleanliness.

“You are not satisfied with my idea as to the manner in which the ammonia acts. I put it forward with diffidence, as very little is known on the subject; but if it is not the true one, it, at any rate, seems the most probable explanation. Ammonia, added to tannin or pyro in solution, causes discolouration of the same kind as is produced by the addition of nitrate of silver; and if this action takes place on an exposed plate, the appearance of the image takes place in a very similar manner, and is of the same colour. The chief difference is, that tannin and ammonia develop much more energetically than tannin and nitrate of silver.

“The difference between the energy of ammonia and nitrate with pyro is not so great; gallic acid with ammonia is intermediate in effect between tannin and pyro, when all are used with ammonia. In Mr. Leahy's experiments the development was produced by the action of the ammonia on the tannin. Mr. Hurst's theory that the ammonia only acts in making the developer penetrate cannot be right, as, with the collodion I use, the strongest solution of pyro will produce scarcely any trace of an image—usually no perceptible trace, in a quarter of an hour—the liquid containing enough alcohol to make it completely penetrate and whiten the film immediately, whilst the addition of one thirty-second of a drop of ammonia will cause the image to start out in all its details in a few seconds.

“The subject is rather obscure; I do not understand the action of heat with tannin alone; heat will discolour pyrogallie solution, but I think not tannin.”

Regarding the question of development, we differed from so careful an observer as Major Russell with considerable diffidence; but we felt that his view of the theory did not

account for all the known facts. At present we offer no theory, but wish for further evidence. The subject is a new one, and may prove wider in its suggestiveness than at present appears.

Scientific Gossip.

EXHIBITION OF COLOURED FLAMES TO AN AUDIENCE.—ILLUMINATING A LABORATORY WITH YELLOW LIGHT.—ESTIMATION OF ORGANIC MATTER IN WATER.—READY FORMATION OF BINOXIDE OF HYDROGEN.—EXAMINATION OF COLOURED GLASS.

AN easy way of exhibiting to many persons at once the striking phenomena of coloured flames, has long been wanted. Some metallic compounds need simply to be placed in a colourless gas-and-air flame on a platinum wire, for them to evolve the characteristic colour in sufficient copiousness to be plainly visible to a large audience; of these, sodium and its compounds, must be first mentioned, the readiness with which they give rise to the well-known yellow light being often painfully antagonistic to other experiments of this character; next follows lithium, the vividness of whose red light (when not eclipsed by the accompanying soda) is almost equally striking, and then perhaps may be ranged barium, strontium, &c. By employing, according to Mr. Crookes' suggestion, the various metallic chlorates, considerably better results may be obtained, but for demonstrations to an audience this plan is hardly applicable, in as much as the light, very vivid though it be at the time, is too much of a flash. What is wanted is some means of evolving a steady uniform light from each peculiar metal, unminged with any other colour. Messrs. Wolf and Diacon have lately proposed a plan which seems to fulfil all the desired conditions in a very perfect manner. They state that on passing a current of hydrogen through a slightly bent tube containing a volatile body in the lower part of the bend, and heating this strongly, the gaseous jet escaping at the open extremity is charged with the vapours of this body, increasing in quantity with the increased heat applied to the tube. By igniting the hydrogen a coloured flame is produced, which in some instances becomes dazzling, when the combustion is stimulated by a jet of pure oxygen.

Many metallic chlorides, but especially alkaline metals, and their volatile compounds, produce, under these conditions, perfectly distinct, and very lasting coloured flames, by placing in the tube a sufficient quantity of material. Upon examining these flames in the spectroscope very curious appearances are produced. A globule of sodium heated in an iron tube, through which a hydrogen current is passed, gives an intensely bright jet, in the spectrum of which appear six well-defined rays, all being clearly marked upon a slightly coloured ground. This ground is not continuous, but has two sudden variations in intensity; the first of these tints is remarkable for its correspondence with a green line, which appears to depend upon the existence of an excess of sodium vapours. By raising the temperature of the iron tube so as to increase the quantity of metallic vapour carried off by the hydrogen, the green band makes its appearance, limited by a very fine green line between β of calcium and δ of barium, and at the same time is observed the effect, remarked by Fizeau, the reversing of the brilliant yellow ray, due to the sodic vapours, surrounding the flame. Potassium, slightly heated under the same conditions gives a magnificent flame, which can easily be maintained for a long time by the successive addition of metallic globules. The rays composing the spectrum of this metal are ten in number, and have for the most part been described by MM. Grandeau and Debray. When potassium and sodium are introduced together into the tube, the spectrum of the potassium at first appears alone, but as it fades the sodium rays appear with glowing intensity. By observing the two spectra thus superposed, it is easy to decide upon

the relative position of the rays of the two metals. It is then seen that the blue lines of sodium and potassium in no way coincide. In trying their experiments they had no metallic lithium, but the same method applied to the chlorides of the preceding metals having given very clear spectra, though not so brilliant as with isolated metals, these experimenters were enabled to replace this metal by one of its volatile compounds. Instead of the iron tube, a small tube was used formed of platinum plate rolled round on itself; by heating in it pure chloride of lithium, four characteristic and very brilliant lines are obtained, one of the lines, a blue one, corresponding almost exactly with the faintest of the two blue caesium lines. Numerous experiments made upon these various bodies, and particularly on sodium, yielded identical results, whatever method was employed to volatilize either the metal or one of its compounds. By using sodium electrodes in Ruhmkorff's induction apparatus, the sparks exhibit all the above-mentioned rays, on which is superposed the spectrum of the circumambient gas whenever the spark is accompanied by a luminous atmosphere.

Volatilisation in a hydrogen current seems to be applicable generally. It has been successfully applied to chloride of calcium; and though with chlorides of strontium and barium, which are not sufficiently notable, the results are not superior to those obtained by the ordinary method, it is very successful with the chlorides of copper, zinc, &c., which give spectra so distinct and intense as to render the study of them exceedingly easy. With some metallic compounds this light is so brilliant that it may be advantageously employed for the projection of the phenomena on to a screen for lecture demonstrations.

To the photographer these results possess considerable interest. The hydro-sodium flame is luminous enough to illuminate a laboratory with brilliancy, whilst its actinic power is absolutely *nil*. It would thus be invaluable in the photographer's dark room; the only drawback would be the alkaline character of the vapours arising from the combustion. These could, however, be easily removed by a chimney.

Organic matter in water is always a serious impurity, but few suffer so much from its presence as photographers. Dr. Woods has recently devised a very simple method of determining the amount of organic matter so present, which appears likely to be useful. The method is based upon the reducing action exerted by the organic matters dissolved in the water upon permanganate of potash, employed as a standard solution. A litre of water is mixed with a decided excess of pure sulphuric acid, and warmed in a porcelain basin to a temperature of 140° Fahr.; the solution of permanganate is then added, drop by drop, from the burette, until the pink tinge is permanent for half an hour. The "chameleon solution" contains one milligramme of crystallised permanganate in a cubic centimetre of distilled water; with this strength, the water supplied to Chatham requires from 2.4 to 7.5 cubic centimetres to produce a permanent coloration. It is necessary to exclude the interfering influence of iron in the state of protoxide, so that when this constituent is present the water should be evaporated to dryness, the residue ignited, dissolved in sulphuric acid, and reduced by sulphurous acid, when the same standard solution will give the amount of iron, and a deduction can be made accordingly. Thus in possession of a method of determining the amount of organic matter of a transitional nature or reducing character, it becomes necessary to institute a standard of comparison, for it would be practically impossible in each instance to identify the kind of organic impurity. Dr. Woods selects for his standard oxalic acid, and with weighed quantities he estimates the volume of permanganate required to destroy it; the results of analysis are therefore stated directly in accordance with this standard, and can at any future time be translated whenever the specific character of the organic matter present in any other sample shall have been ascertained. As instance of the kind of

results obtained by this method sewage water, and a sample drawn from a pump in the neighbourhood of a cesspool have been tested by this method; the latter was found to contain no less than five grains of organic matter (oxidisable) in the gallon. Photographers would do well to practise this simple kind of test occasionally, for oxidisable organic impurity is especially injurious in their operations.

Somewhat allied to the subject of purification of water is the formation in a ready and cheap manner of binoxide of hydrogen, which has just been accomplished by Mr. Duprey. By passing a very rapid current of pure carbonic acid into distilled water, and adding at intervals binoxide of barium, perfectly pure oxygenated water is obtained. When the quantity of carbonate of baryta is sufficiently large to obstruct the passage of the gas, the clear liquid containing all the oxy-water must be decanted, and the current of carbonic acid again passed into it.

As soon as more binoxide of barium is thrown in, a fresh quantity of oxygenated water is formed. In this way we obtain water strongly charged with perfectly neutral and pure oxygenated water, which can be concentrated under an air pump. Care must be taken to maintain a sufficiently rapid current of carbonic acid so as always to be in excess of the small and gradually added binoxide of barium, which must, moreover, be finely powdered, as large pieces escape decomposition. The carbonic acid must be washed carefully by passing through flasks containing carbonate of lime. The best re-agent for oxy-water is decidedly permanganate of potash which, poured into water containing even a very small portion of oxygenated water, disengages all its oxygen. This body serves, therefore, to estimate oxygenated water as well as organic matter, the phenomena of decoloration being very apparent.

Three samples of glass have been sent for examination in the spectroscope. No. 1 (S) is of a brown colour, and admits of the passage of several active rays. It is, therefore, inapplicable for photographic purposes. No. 2 (F. Lane) is of an orange colour, and, in the instrument, appears almost perfect. Some few actinic rays, however, struggle through. No. 3 (Mr. Wilkinson) is similar in colour to No. 2, but a trifle darker. As a photographic screen, it is excellent, the whole of the active rays being cut off by it.

SPIRIT PHOTOGRAPHS.

CONSIDERABLE interest is at present excited in certain circles in America by the alleged production of photographic portraits of disembodied spirits! We alluded to the subject in a recent paragraph, as a *canard*. We now find a good deal of matter on the subject, collected from various sources, in the *Spiritual Magazine*; and as photographers generally will be concerned in preventing their art being made the vehicle of imposture, we give some copious extracts. It is scarcely necessary for us to say that the presence of additional ghostly images on the plate, besides that of the real sitter, is easily compassed. The evidence fixing the identity of such phantom images, and as to the mode of producing them, we leave without comment to the good sense of our readers.

The facts, as narrated by Dr. H. F. Gardner, of Boston, are as follows:—

“Mr. W. H. Mumler, an amateur photographer and practical chemist of Boston, was engaged on Sunday, October 5th, at the photograph gallery of Mrs. Stuart, at No. 258, Washington Street, in adjusting the chemicals, which had become disarranged. Having prepared a plate, and placed a chair near the focus of the camera, by which to adjust it, he proceeded to take his own photograph, card size, by quickly jumping into position and standing still the required time. The picture—a copy of which we have seen—represents Mr. Mumler as an active, rather athletic-looking man, standing with his coat off, and the black cloth, used to cover the camera, in his hand. Upon the back of this card appears the following statement:—‘This photograph was taken of myself, by myself, on Sunday, when there was not a living soul in the room beside me—’ so to

‘speak.’ The form on my right I recognise as my cousin, who passed away about twelve years since.—W. H. MUMLER.”

“The form referred to is that of a young girl apparently sitting in the chair, which appeared on developing the picture, greatly to the surprise of the artist. The outline of the upper portion of the body is clearly defined, though dim and shadowy. The chair is distinctly seen through the body and arms, also the table upon which one arm rests. Below the waist, the form (which is apparently clothed in a dress with low neck and short sleeves) fades away into a dim mist, which simply clouds the lower part of the picture. Mr. Mumler affirms that this form bears a likeness to a spirit cousin, and its appearance was equally unexpected and startling to the artist, who was not a believer in spiritualism, though perhaps somewhat interested, and had no reason to suppose himself a medium.

“Since this accidental discovery, we are assured by Dr. Gardner that at least a dozen similar photographs have been taken, a new spirit form appearing at the side of each subject. The artist experiences a loss of strength in the process that limits him to three or four sittings per day. The forms are not as distinct as we could desire, yet they are sufficiently marked to prove individuality to friends. Dr. Gardner kindly left with us two specimens of photographs taken subsequently to the one we have described. They are card photographs of a gentleman and his wife, residents, we believe, of Chicopee. On the picture of the lady stands beside her a female form, recognised by both parents as the likeness of a spirit daughter. The upper portion of the form is quite distinct, but the lower fades out in the form of flowing skirts, partly covering the mother’s dress, till quite indistinct at the floor. The other has a less distinct form, yet one recognised by the gentleman as that of his mother in the summer land. A peculiarity about this picture—less distinct though it is—renders it one of the most interesting we saw. The upper portion of the shadowy figure alone has a recognizable form, and this is so large, that were the figure to be completed in due proportion, the feet would be carried some distance below the floor. It is a magnified image of a human (or spirit) head, hardly possible to have been produced from any visible object within range of the instrument. And the arm of the spirit seems thrown about the neck of the subject (her son), the hand resting like a little cloud of mist upon the opposite shoulder. Witnesses were present, in all cases except the first, to testify that only one person sat for each picture, and yet we are assured that in some instances three additional forms appear. Similar results to those mentioned above can perhaps be produced by any skilful photographer, by introducing forms during a portion of the time a plate is exposed, or reflecting an image upon the sensitive surface in the dark room. We trust scientific and truth-loving photographers will experiment, that, if possible, the fraud or accident, if either exist, may be exposed, or the means made use of by spirits to project an image upon the air exposed to the line of vision of the camera be discovered.”

We next hear that Mr. William Guay, a practical photographer, had undertaken to test and verify this matter. He thus writes on the subject to the *Banner of Light*, a Boston paper:—

“Boston, Nov. 18, 1862.

“MR. EDITOR,—Having been informed by Mr. William H. Mumler that you desire to publish the results of my investigation into the possibility and genuineness of Mr. M.’s photographic impressions of spirit forms, it gives me much pleasure to detail to you what I have seen. As I have been commissioned by Messrs. A. J. Davis and Co., you can rest assured that I was resolved, if permitted, to allow nothing to slip my utmost scrutiny. Having had ten years’ continual practice in this particular branch—that is, negative on glass, and positive on paper from negative—I felt competent to detect any form of deception.

“Having been permitted by Mr. Mumler every facility to investigate, I went through the whole of the operation of selecting, cleaning, preparing, coating, silvering, and putting into the shield, the glass upon which Mr. M. proposed that a spirit form and mine should be imparted, never taking off my eyes, and not allowing Mr. M. to touch the glass until it had gone through the whole of the operation. The result was, that there came upon the glass a picture of myself and, to my utter astonishment—having previously examined and scrutinized every crack and corner, plate-holder, camera, box, tube, the inside of the bath, &c.—another portrait.

"Having since continued, on several occasions, my investigations, as described above, and received even more perfect results than on the first trial, I have been obliged to endorse its legitimacy.—Respectfully yours, Wm. GUAY."

"In a letter of the 26th November, after having made a full and minute report of his visits, Mr. Guay reports to Messrs. Davis and Co. as follows:—"The weather has been too unfavourable since Saturday to print from the negatives, on one of which I perfectly recognise the likeness of my father. The picture of my wife is very faint, but sufficient for me to recognize the features. It is impossible for Mr. Mumler to have procured any pictures of my wife or father." He also says that whilst he sat for the two pictures he mentally desired that the likenesses of his father and of his mother should be produced.

"Another photographic artist, Mr. H. Weston, of 31, Province-street, Boston, writes that after making a full examination of the process, he found a spirit-figure on the negative. He also says that he cannot conceive of any process by which imitations could be made without his detection."

(To be continued.)

TONING WITH GOLD AND LIME.*

THE tone of French prints is often very much admired, and we believe they are in the majority of instances produced by a bath containing lime in combination with the gold. We are indebted for the following formula to Mr. Parkinson, of Dieppe, who showed us some very exquisitely toned prints produced by it. He informed us that it was almost universally used among French portraitists. It is by M. Ommeganck, and originally appeared, we believe, in the *Bulletin Belge*; but as we receive it in French MS., we are a little uncertain of its origin. The tones are a rich deep black, quite free from mealiness, blueness, or slatiness in the shadows, and have warm tint in the half-tints, which is very valuable and flesh-like in portraiture. The formula stands thus:—

Chloride of gold.	15 grains.
Carbonate of lime	150 "
Chloride of lime..	23 "
Water	7 pints.

Dissolve in *aqua regia* (nitric acid one part, hydrochloric acid two parts), metallic gold 90 grains; after solution, add 30 grains of common salt to prevent decomposition during evaporation; evaporate by a gentle heat, until the saline mass contains no excess of water. It is not necessary to push the evaporation to complete dryness; a trace of acid is not of much consequence. Dissolve the salt of gold thus obtained in three ounces and a half of rain or distilled water, and you have a solution containing about 45 grains of chloride of gold to the ounce of water. It is not, with this preparation, necessary to weigh every time small quantities are required, nor is it necessary to preserve it from moisture. This salt of gold, generally called chloride, is a hydrochlorate of chloride of gold; the formula stands thus:— $AuCl_2ClH$, in round numbers, metallic gold 200, chlorine and hydrogen 140, together 340; reducing we shall have $10+7=17$; multiplying by 6 we shall have gold 60, chlorine and hydrogen 42, together 102; then 90 grains of gold will yield about 150 grains of the hydrochlorate in question. Two drachms and forty minims of the solution are taken and triturated in a porcelain mortar with 150 grains of carbonate of lime. If it be intended for immediate use, the preparation should be left in contact for one hour; if on the morrow—and this is best—ten minutes will be found sufficient. By this treatment the chloride of gold abandons its acid and a certain portion of its chlorine. The whole of the operations should be conducted by the heat of a water bath, in winter, at a temperature of between 70° and 80° Fah. Carbonate of lime being nearly insoluble, a slight excess of it is not so important as an excess of carbonate of soda. The reaction being completed, 28 grains of chloride of lime (hypochlorite of lime) are added; this latter salt should be specially pre-

pared and preserved in closely-stoppered bottles, on account of its tendency to become humid and decompose in damp air. After that add 35 ounces of water, filter, and then add 5½ pints more water, and preserve in stoppered bottles. When this bath loses its toning properties through age, without having been exhausted, it may be restored by the addition of about four drops to the pint of a ten per cent. solution of chloride of gold. When the bath has lost its smell, it may be restored by adding a few drops of a fresh solution of chloride of lime. Either this or a few drops of solution of chloride of gold will restore its action after it has been partially used, and has grown inert.

On immersing the print in the hypo bath, the tone of the proof changes at once to a violet brown; but, as soon as it is properly fixed, it returns to a bluish black. Finally, the prints are washed, as before described. The hyposulphite bath should only be used once.

ON THE COAGULATION OF ALBUMEN.

BY M. MC. A. GAUDIN.*

[We are glad to find that M. Gaudin has been following up and verifying our experiments on the coagulation of dried albumen. His further suggestions may be valuable if they prove true in practice.]

THE familiar fact of the coagulation of albumen, manifested every day in the cooking of eggs, has probably greatly contributed to lead chemists, as well as photographers, to believe, that dried albumen possesses the same property of coagulation; hence the directions given, and doubtless frequently followed, of passing a hot iron over albumenized papers before sensitizing them on the nitrate of silver bath. The precaution of ironing the paper is taken to coagulate the albumen, and prevent it from leaving the paper and mixing with the bath.

During the past few months many articles have appeared in the photographic journals tending to prove that albumen, previously dried, no longer undergoes coagulation by heat; but this absence of coagulation, which means that albumen continues easily soluble in water, was not in this way clearly explained; and this it was that decided me to prove the truth by experiment.

I took white of eggs dried spontaneously, having the appearance of dry transparent scales of a straw colour; I dissolved a portion in warm water. The solution soon formed a viscid liquor, and was quickly converted into froth by beating. I wrapped another portion in paper, and exposed it for an hour in an oven heated to the temperature of boiling water, where the portion previously dried had become a solid mass. The dried albumen thus heated became entirely dissolved, forming a frothy liquid, exactly as if it had not been exposed to heat, consequently, dried albumen loses none of its solubility by being exposed to the (dry) temperature of boiling water.

In order to ascertain whether the result would be the same if the albumen were exposed to a higher temperature, I wrapped another portion in paper and placed it in a sand-bath, so hot as to scorch the paper and the albumen enclosed in it. At the close of the experiment the greater portion of the albumen was scorched, emitting the odour of burnt egg.

In this instance warm water dissolved the unscorched egg, leaving the scorched portion intact; and upon heating the liquid to ebullition, it remained limpid, even ceasing to froth, immediately absorbing its bubbles as soon as the vessel was withdrawn from the fire. From this we must conclude, that albumen, previously dried, remains entirely soluble in water, whatever the temperature to which it has been submitted, providing this temperature is not high enough to scorch it, or cause decomposition to commence; and albumen, intact, but burnt, ceases to be coagulated by heat even after it has been dissolved again.

Dried albumen, dissolved without being submitted to heat,

* From an article on "Methods of Toning" in our YEAR BOOK OF PHOTOGRAPHY FOR 1863.

* La Lumiere.

is coagulated by heat; but I have noticed that, by this simple desiccation, it does not dissolve as readily as albumen fresh from the egg, which compels me to conclude that any degree of desiccation weakens the faculty of coagulation.

From this it results that the passing a hot iron over paper covered with dried albumen produces no effect, and that the presence of water is essential to obtain coagulation. In all probability, a minimum quantity of water suffices to produce this phenomenon; as to the paper, if already dry, it is sufficient to place it in a cellar, or other damp place, for a time, for the albumen to become coagulated by the passing of a hot iron over it.

To render albumen in the dry state insoluble, we must have recourse to chemical actions. Dry albumenized paper immersed in absolute alcohol, abandons its albumen to water as soon as the alcohol is evaporated; concentrated gallic acid no longer producing any effect on it. It is different with the metallic salts: the salts of silver and of mercury, for instance, produce insolubility. With the albumenized papers in a dry state this is an essential point, as they must always be sensitized on the silver bath before they can be used, only it would be preferable for the albumen to be coagulated in advance; and if, heretofore, the passage of a hot iron over the dry paper was in reality without effect, it is now certain that on performing the same operation at the proper moment, that is, while the coating of albumen is still moist, or is rendered so by exposing the dried paper in a damp place, an excellent effect will result, which absolutely prevents the separation of the albumen, which so frequently spoils the silver baths. For the preparation of albumen on glass, it will be also useful to take this experience into account by submitting the coated plates to a degree of heat suitable to coagulate the albumen, before they become completely dry, so as not to take this trouble in vain, inasmuch as the introduction of albumen into the bath is much more mischievous in this case than in the other.

Albumen is an organic substance, the complexity of which has remained hitherto impenetrable to chemical investigation: in all probability its molecule is composed of a great number of atoms, (since sulphur forms a part, yet cannot be separated, because its proportion is so small,) then its weight is considerable: and it is this that induces me to say that a very small proportion of water suffices to promote its coagulation. This useful proportion is actually disengaged only when the desiccation has arrived at its last limit, and we can be certain of succeeding in coagulation only when the paper appears not quite dry to the touch.

[The amount of moisture necessary to secure the conditions for coagulation is an interesting subject for inquiry. Mr. J. W. Osborne recently remarked to us, that in the preparation of his photolithographic transfer, he has observed, that when the paper, coated with gelatine and albumen, was floated on boiling water, face upwards, no coagulation of the latter took place at boiling heat until the whole had become thoroughly permeated with moisture, and that, by observation and experience only, could the proper time be determined.—Ed. P. N.]

PHOTOGRAPHY IN THE POLICE COURT.

PHOTOGRAPHY and photographers have recently been figuring in the police court. Besides the recent copyright infringements, there have been, within the last week, two or three criminal cases, which we give as reported in the daily papers. The first was before Mr. Elliot, at Lambeth, and stands as follows:—

ROBBERY AT THE CRYSTAL PALACE.—*George Restall*, a young man, who has been manager of the business—in the Crystal Palace—of Messrs. Negretti and Zambra, was charged with stealing thirteen lenses of the value of £60, the property of his employers.

Mr. H. Negretti deposed that the prisoner was employed by his partner and himself to conduct their business at the Crystal Palace, at a salary of £3 a week, and about a fortnight since

he came to them and said he had missed as many as nineteen lenses from his stall in the palace, and mentioned the name of a party whom he suspected. He (witness) told him at once to communicate with the police at the palace; but instead of doing so, he gave information of the alleged robbery at Scotland-yard, giving as his reason that the police of the palace were too friendly with the suspected party. Three of the four lenses produced were the property of witness and his partner, and were a portion of those missing.

A shopman to Mr. Blizzard, pawnbroker, in the Borough, produced the four lenses, and said that they had been pledged with him by the prisoner, who described them as his own property.

Sergeant Palmer, a detective, said that about a fortnight ago he received instructions to make inquiries respecting thirteen lenses stolen from the Crystal Palace. He saw the prisoner on the subject, and in his account about the lenses he said they were safe about three weeks ago, though in his information he mentioned that they had been gone six months. He asked him if he pawned them, or either of them, when he not only positively denied having done so, but declared he had never been in the shop of a pawnbroker in his life.

The prisoner, who denied the charge, was remanded to a future day.

On Tuesday last the case was again heard, when Mr. Sleight appeared for the defendant, and Mr. Lewis, jun., for the prosecution.

Mr. Negretti said that since the last examination he discovered other lenses missing, and requested a further remand, to give time for tracing the other property, and which, with that produced, was of the value of from £90 to £100.

Mr. Sleight represented the prisoner as a person of high respectability, and he felt quite sure, incapable of committing the offence attributed to him, and examined the witnesses at some length, after which the prisoner was again remanded, but admitted to bail.

We sincerely hope that at a future hearing Mr. Restall may be able to prove his innocence, as we know him to be a skilful photographer, and should be sorry to think him a dishonest one. The next case was heard at Marlborough Street, before Mr. Tyrwhitt, and stands thus in the report:

THE MAJOR AND THE PHOTOGRAPHER.—*Winter Thompson*, photographer, Oxford-street, was summoned before Mr. Tyrwhitt for assaulting Major Lister.

The evidence of the major went to show that he went to the defendant's with his wife and child, six years of age, to have the latter's portrait taken, and there saw a female, who said that if the first portrait taken was not approved of, a second should be taken, there being also a notice up to a similar effect. A portrait was taken, but as the child's head, owing to the position in which the child was placed, was sunk between its shoulders, he objected, and asked for another; but the artist rudely objected, said it would do very well, and on his going down stairs, declining to go on with the transaction, a man (Mr. Thompson, jun.) rushed out of a door on the left hand side of the passage, and pushed him back, threatening to knock him down. Another man (the defendant) then rushed out of another room and seized him by both hands. The defendant then retired, at his son's request, and an altercation of a violent nature on the younger Thompson's part ensued, in the course of which he said that he was justified in detaining him (the major), and taking his life. The cost of the portrait was to be half-a-crown.

Mr. Edward Lewis, of Great Marlborough-street, for the defence: The major said that he had been to the Messrs. Southwell's, the photographers, previously, but was perfectly satisfied with the reception he there met with. Mr. Thompson did not say that if he pointed out any fault he would do another. He did not wait for the photograph, and only was reluctantly shown the negative.

Mr. Thompson, jun., was called as a witness for his father, and said the complainant would not point out any fault in the negative, but peremptorily refused to have the portrait, and refused to give his name and address, or to pay the 2s. 6d. for it.

A young woman named King, in the employ of the defendant, said that the major wished to arrange the child himself, and would not let the artist do so. Mr. Thompson, jun., did not push him, and Mr. Thompson, sen., rushed out of the room, and said the major should not strike his son.

Robert Cousins, artist to the defendant, said that he told the major that he was not a judge of a negative, as he was not a photographer, and the major then went off in a tiff.

Major Lister said he should like to ask the artist if there was not a notice up, stating that if the first portrait was not approved of a second would be taken.

The witness said that was the case, but the portrait had not been shown the complainant, only the negative.

Mr. Tyrwhitt said he thought the complainant had been too hasty in the matter. He did not see, until the positive was taken, how any person could be a judge of a portrait. He thought there was a misunderstanding altogether, and should dismiss the summons.

On the same day, at Guildhall, there was another case, with no further photographic interest than that it was a robbery in a photographic establishment.

CASH ROBBERY.—George Bates, a porter, lately in the employ of Mr. Newcombe, of the London School of Photography, 103, Newgate-street, was charged before Alderman Humphrey with breaking open his master's cash-box, and stealing therefrom £160.

Inspector Wilson, of the C division, said the prisoner surrendered himself at the Vine-street Police-station; and after receiving the usual caution, he was told that the charge against him was for robbing his employer of £160. He then stated that he broke open the cash-box and took away the money, but that while proceeding to Bristol he was robbed of the greater portion of it. He also said he had twice contemplated suicide, but that he could not muster up courage enough to destroy himself.

Wm. Joseph Anderton, the manager of Mr. Newcombe's establishment in Newgate-street, said the prisoner had been in their employ about twelve months, first as porter, and afterwards as assistant in preparing the materials for the use of the artist. His wife was also housekeeper in the same establishment, and lived with the prisoner on the premises. On the night of the 25th of November last he put £150 into the cash-box, and put the key on the top of the safe, and when he arrived on the following morning he discovered that £157 19s. 4d. in gold and silver was gone, but that a large amount in notes, cheques, and postage-stamps, had been left behind. The cash-box had been forced, and, as the prisoner absconded very suddenly on that day, suspicion fell upon him.

Mr. Martini, the chief clerk, said a warrant was issued from this court on the 27th of November, for the prisoner's apprehension.

Alderman Humphrey asked what had become of the prisoner's wife? Witness said she and her two children had been in the Bow Union ever since the prisoner went away.

Alderman Humphrey asked the prisoner what he had done with all the money?—The prisoner replied that he did not wish to answer any questions, as he admitted he was guilty.

Alderman Humphrey inquired what sort of character the prisoner had previously borne?—Witness said he came from Mr. Greer's, the cutler, in Newgate-street, with an excellent recommendation. He had also held the situation of engine-keeper and organ-blower at Christ Church, Newgate-street.

The prisoner was remanded.

The International Exhibition.

REPORT OF THE JURY ON PHOTOGRAPHY AND PHOTOGRAPHIC APPARATUS.*

EARLY HISTORY OF THE ART.

THE present gathering of works in Class XIV. of the International Exhibition will mark an epoch in the history of photography. For the first time, in the crescent of all the arts and sciences, it is recognized as an independent art.

In the London Exhibition of 1851, sun pictures were grouped with philosophical instruments; in the Paris Exhibition of 1855, with printing and applied design; so that, in the first, a photographic landscape was supposed to hang in its proper place, behind a sextant or a voltaic battery; in the

second, among paper-hangings, candlesticks, and children's toys. That era of confusion has now been passed, and photography has obtained a distinct place in the arts—it is admitted to rank as a separate class.

As this public reception of photography into the great sisterhood of the arts will close the first period of its existence, and open a new and larger field of endeavour, it may be well to recall very briefly a few leading facts of its public history up to the state at which the present report will have to make a more minute and technical record of its efforts.

Photography, as a practical art, only dates, as it were, from yesterday, though some of the natural laws through which it works were subject to investigation and speculation in ancient times.

Three hundred years before Christ, Ruelid appears to have observed the principle of the stereoscope, and Galen, subsequently, in his work "On the Use of the Different Parts of the Human Body," has fully described the various phenomena which occur when viewing any body with both eyes, and then, alternately, with the right and left. Mr Hunt has traced, with much zeal, in his "Manual of Photography," the progress of the discoveries of the various minds by which the art has been built up, and describes the researches of Liectus and Kircher, in 1646, on the phosphorescent influence of the sun's rays. That Petet, in 1722, found that solutions of nitrate of potash and muriate of ammonia crystallized more readily in light than in darkness. In 1777, the illustrious Scheele gave, in the following account, the first philosophical examination of the peculiar changes in the salts of silver, and showed the dissimilar powers of the different rays of light in effecting their change. He says:—"It is well known that the solution of silver in acid of nitrate poured on a piece of chalk, and exposed to the beams of the sun, becomes black. The light of the sun reflected from a white wall has the same effects, but more slowly. Heat, without light, has no effect on the mixture. Fix a glass prism at the window, and let the refracted sunbeams fall on the floor; in this coloured light put a paper covered with luna cornea, and you will observe that this horn-silver grows sooner black in the violet ray than in any of the other rays." Senebier repeated and extended similar experiments in 1791. Fischer added to our knowledge in 1795. Count Romford published, in the "Philosophical Transactions" of 1798, "An Inquiry Concerning the Chemical Properties which have been Attributed to Light;" but Mr. Robert Harrop published, in "Nicholson's Journal," in 1802, a communication in which he negated the experiments of Count Romford, and proved that the actions described by him were due to light, and not to heat.

In June, 1802, Sir Humphry Davy published, in the "Journal of the Royal Institution," an "Account of a Method of Copying Paintings upon Glass, and of Making Profiles by the Agency of Light upon Nitrate of Silver." Sir Humphry Davy had conjointly experimented with Mr Thomas Wedgwood, considerable success attending their researches, and Sir H Davy concludes with this observation:—"Nothing but the preventing the unshaded parts of the delineations from being coloured by exposure to the day is wanting to render the process as useful as it is elegant." Wedgwood and Davy failed entirely to fix the produced image; and, with the exception of some further contributions to our aid from Drs. Young and Wollaston, no great step was made until 1814, when Joseph Nicéphore Niepce made the first permanent successful result. He named his process "Heliography," and in 1827 he presented a paper to the Royal Society on the subject; but as he kept his process then as a secret, it was not received. The memoir was accompanied with several specimens of his success on plated copper and pewter, and were afterwards distributed amongst his friends in London. By the favour of Mr Joseph Ellis, of Brighton, an opportunity has lately been afforded to closely examine one of these specimens. It is the copy of an engraving produced by the action of light in a camera on a layer of bitumen covering a silvered plate of pewter. It is not altogether in effect unlike a Daguerreotype, but wanting in the unpleasant metallic brilliancy, and having considerably more depth of tone in the shadows, which, it is stated, was produced by a subsequent application of the vapour of iodine. This specimen had been given by Niepce to his landlord, when he resided at Kew, and is so inscribed. The patient and persevering endeavours of Mr Ellis, who is the author of an instructive work, "The Progress of Photography," to procure this specimen, and save it from oblivion, are well worthy of praise.

The processes of M. Niepce were afterwards published, and he appears to have entered into a sort of partnership with M. Daguerre, who, in 1824, began a series of experiments with a view of fixing the pictures which had been taken in the camera; but it was not until the 7th of January, 1839, that Daguerre made his communication to the Academy of Sciences of his invention of the process known as the "Daguerreotype."

Mr. Fox Talbot, of Lacock Abbey, who had experimented since 1833 in photographic researches, on January 30th in the same year, 1839, communicated his discovery to the Royal Society of his process for multiplying photographic impressions, and which were then generally known as photogenic drawings. The investigations in France, by M. Daguerre, and of Mr. Fox Talbot, in England, were perfectly independent of each other.

The Rev. J. B. Reade, in April, 1839, took pictures of natural history by means of the solar microscope. Nitrate of silver was employed to sensitize the paper, and a solution of nut-gall washed over just previous to use: the paper being used wet, considerable sensitiveness was thereby secured. In the same year, 1839, on the 29th of May, Mr. Mungo Ponton made a communication of great importance to the Royal Society of Arts of Scotland, on the use of bichromate of potash. Sir John Herschel also used glass plates at this period, and published several valuable papers on the progress he had made towards the development of photography.

It was not until February, 1848, that Mr. Fox Talbot patented the process which, for a long time, bore his name, and which was subsequently changed to that of Calotype.

Recording merely the names of Mr Hunt, Dr. Draper, M. Bequerel, M. Claudet, M. Bayard, M. Niepce, Mr. Candell, Dr. Wood, Professor Wheatstone, Sir David Brewster, and others, we come to that of Mr. Archer, who, in 1851 just before the opening of the Exhibition in that year, published his collodion process. Although albumen had been extensively used, it never became popular, and, with the exception of Ross and Thompson, of Edinburgh, some few in England, M. Martens, M. Ferrrie, and a limited number in France, it did not maintain its position, chiefly from its great want of sensitiveness, and the greater facilities afforded by collodion. Previous to the Great Exhibition of 1851, it will be recollected that no collodion pictures were publicly exhibited; and we are exclusively indebted to the late Mr. Frederick Scott Archer for his application of collodion. Although very many details have been perfected, and many labourers have devoted hours in successful improvements, it must not be forgotten that Archer published his

* The following gentlemen constituted the Jury:—High W. Diamond, M.D., F.S.A., Secretary, London; A F J Claude, F.R.S., London, Photographer; Baron Gros, Chairman, France, Senator; Lord Henry Lubbock, M.P., Deputy Chairman, London; C T. Thompson, London, Official Photographer, Science and Art Department; assisted by B. Delessert, France; Lieut.-Colonel Demanet, Belgium, Member of the Department of Fine Arts of the Royal Academy of Belgium, as Associates.

collodion process—a truly useful and practical one, which, even up to the present time, cannot be said to have received such aid from any single contributor as to detect from the greatness of his first application. At what date Mr. Archer first used collodion is unknown; but this much is certain, that he first explained the process to his friends on the 21st September, 1850, at which time he was as well acquainted with its valuable properties as he was at the time he published it in March, 1851, in *The Chemist*.

Mr. Archer had been brought up at a silversmith's, but, not liking his occupation, some friends succeeded in placing him in a position more congenial to his feelings. He commenced as a sculptor, and wishing to preserve for himself records of the works which he had executed, induced him to study photography. For some time he had used the calotype process of Mr. Fox Talbot, to which he was the first to apply the pyrogallic acid; but he complained of the difficulty in procuring paper suitable for his work, and, with a view to form a finer surface to the paper, he first covered this iodized paper with collodion, and afterwards sensitized the paper by entire immersion.

The next thought was to combine an iodide direct with the collodion, and apply the collodion to glass. In his early instructions and practice, the collodion film was always removed by Mr. Archer from the glass on which the picture was taken.

It has been stated by some that M. Le Gray, in Paris, about the same time, and quite independently, also conceived the idea of improving the surface of paper with collodion. Whatever question there may be about this application of it, there is none whatever that the application of collodion to glass alone was an original and prior thought and application of Archer's. Mr. Archer, although possessed of many gifts, did not possess that of delicacy of manipulation, and, at the same time, he was always more anxious for research than the taking of photographic pictures; hence some of his friends succeeded far better than himself in obtaining satisfactory results from the process he had invented. It is satisfactory, as clearly establishing how little success had attended M. Le Gray's practice, that Mr. Archer applied to a friend, in the early part of 1852, for some specimens to forward to Paris, to prove what good results might be obtained with collodion under ordinary care.

(To be continued.)

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 31st December 1862.

At the last meeting of our Photographic Society, a communication from Dr. Sabattier was read, on the means of obtaining direct positives on glass. He says:—"At the meeting of the Society in July last, when my note on direct positives obtained by the aid of diffused light was read, the President remarked, that in order to be able to judge of a process, an essential condition is to have its products before our eyes, and invited me to send some proofs in support of my communication. In reply to this invitation, I now send the Society a dozen of my pictures. It would have been easy for me to have sent a much greater number, but as it is sufficient to have well defined the circumstances under the influence of which is manifested a phenomenon which can be repeated indefinitely, it seemed to me that this dozen pictures will establish, indisputably, that we can constantly and regularly, by flooding it with light, convert a negative, sketched in the darkness of the operating-room, into a positive.

"These pictures, are, it is true, not free from defects; but the competent judges to whom I now submit them, will readily perceive that the defects must be attributed to the operator, and not to the process.

"In the hands of an operator better acquainted with photographic manipulations, the process will satisfy all the requirements of the art. A very few experiments will serve to convince the most sceptical.

"I cannot too often repeat, that nothing can be easier and simpler than to make a direct positive, while at the same time nothing can be more curious. As the materials and the manipulations remain the same, without any new baths or washings, by merely giving access to diffused light at a certain moment, we suddenly convert the faint negative into a positive.

"In my previous communication, I announced three conditions as indispensably necessary to the manifestation of this phenomenon.

"1st. To give access to diffused light before the negative arrives at its perfect state.

"2nd. To sensitise with a perfectly neutral bath.

"3rd. To develop with pyrogallic acid, to which acetic or other acid, not too energetic, is added.

"Recent experiments have shown me that the second of these conditions, deduced from misinterpreted facts, is not indispensable; that we can as easily obtain positives with an acid sensitizing bath, as with one that is neutral, which latter, however, gives the best results.

"Two conditions only are therefore essential, and they are easily fulfilled. For every photographer, who is not prejudiced, but sensible of the attractions of the art or science he cultivates, can experiment, see with his own eyes, and touch with his hands, the most surprising phenomenon his art can show."

The pictures sent by Dr. Sabattier excited much interest, and the thanks of the Society were awarded to him for his communication.

M. de Poilly exhibited to the Society a new system of apparatus, permitting the working of wet collodion without exposing the plate to light. He remarks that—

"Collodion, the basis of the photographic processes called *instantaneous*, has not yet received its full extension outside the operating room; hence it follows that a tent has hitherto formed an indispensable piece of photographic luggage.

"To be able not only to lessen the material, but also to simplify photographic operations, so that the merest tyro may operate with the same certainty as the experienced artist; to be able to operate without a dark room of any sort, as well at home as abroad—such are the advantages presented by my apparatus.

"Hitherto travelling photographers have been obliged to operate under tents, and to carry with them a load which it is not always easy to transport from place to place, or suitably dispose of at the scene of operations. With my system of apparatus, wherever the camera can be planted, my new dishes find their place, and the operations proceed mechanically, so to speak, and with remarkable celerity.

"To be able to operate without laboratory or tent, I have invented for each photographic operation a compound apparatus, in as many pieces as there are operations to perform in obtaining a picture. "*Sensitizing Apparatus*.—This is a bath employed in sensitizing the collodion film with nitrate of silver. Its form gives it many advantages over vertical and horizontal baths, without possessing any of their inconveniences. Thus, it requires only the liquid of an horizontal bath while the plate is covered with nitrate, as instantaneously as with a vertical bath, and this is done with the aid of a handle which suspends this bath under the base of the camera obscura, and admits of its turning, so as to assume the necessary positions:—1st, for introducing the plate; 2nd, for its immersion; 3rd, for draining it; 4th, for removing and conveying it into the slide; all without any loss of liquid, and without its having received any photographic light. In this and the succeeding operations the are not soiled, or stained by the solutions. This bath is suspended by its handle beneath the base of the camera, in an horizontal position; before immersing the plate it is placed vertically, and is fixed in this position by a hook. The quantity of solution judged necessary to introduce into the bath—a quantity which must never exceed that requisite for an horizontal bath—collects at the lower end of the bath. While it is in this position the collodion plate is introduced, the collodion side towards the operator; the bath is then shut, the hook unfastened, and the bath immediately resumes its horizontal position. The solution collected at the bottom of the bath covers the collodion plate in an instant. The bath is then rocked, to allow the ether to evaporate, and when the plate is supposed to be nitrated, the bath is again placed in a vertical position, and held there by the hook. The solution now flows to the bottom of the bath again, and the plate is found in its first position, which permits it to drain before being passed to the slide.

"*The slide*.—In this position the slide of the camera is adapted to the bath by the aid of grooves; this done, the slide and the bath are opened, and unhooked; the

whole revolves towards the operator. By this movement the plate places itself in the slide, and the liquid flows into the reservoir. The slide is then closed, the bath removed, and the plate is now ready for exposure in the camera. When it is desired to shut the bath hermetically, the vulcanized cover is screwed on, as in ordinary vertical baths.

Apparatus for Developing Baths.—Upon leaving the camera, the picture, as is well known, exists only in the latent state. I have therefore been led to construct a bath made so as to receive the plate from the slide, after its exposure in the camera, without its being attackable by the external photogenic rays; to develop and watch the appearance of the image in its different stages; and lastly, to wash it, and allow it to be withdrawn only after its complete appearance. Upon removing the slide from the camera, it is adapted to this bath by means of grooves, and the quantity of developing solution introduced requisite to cover the plate; the covers are then opened, and the plate slides into the bath. As soon as it reaches the bottom, it is rocked, as generally done; and upon opening the bottom of the bath, employing a reflector, and examining it by light admitted through a yellow glass, we follow the operation step by step. When satisfied with the result, the liquid is rejected; the picture is then washed, withdrawn from the bath, and fixed."

M. de Changy presented to the Society his new arrangement for positive printing frames.

These frames differ essentially from the ordinary ones, inasmuch as the screws and springs usually employed to press the negative and printing paper together, are suppressed. To replace these, the inventor has placed under each bar of the back of the frame four india-rubber springs, arranged perpendicularly to the bars, and which, by their elasticity, assure an equable, gentle pressure. In another system of frames, the bars, furnished with the same kind of india-rubber springs, are armed on their upper part with an eccentric lever, which, upon being turned, permits of the gradual exercise of a strong pressure upon the glass.

M. Stephen Geoffray communicated some observations upon the employment, as recommended by himself some years ago, of the iodide of carbon in the solutions of spirits of turpentine and of benzine, of which some photographers make use in the preparation of negative paper. This substance possesses great advantages, for it is soluble in these two vehicles, which the alkaline or metallic iodides are not.

The President, while recognizing that the organic iodides might be advantageously employed in this case, feared that M. Geoffray was in error with regard to the nature of the compound sold to him under the name of *iodide of carbon*, for hitherto the iodides of carbon have only been prepared in the laboratory.

M. Geoffray said, that the product in question was in the form of a yellow powder, slightly crystallized.

From this description the President thought it must be iodoform.

The President then reminded the Society, that on the 1st of May, 1863, the bi-annual Exhibition of the Fine Arts would be opened. Without being able at present to state what would be the conditions of this exhibition, the Committee of administration is already in a position to inform photographers that, according to the practice adopted in former years, the exhibition of the French Photographic Society would figure side by side with that of the Fine Arts. The President considered it his duty to invite the members of the Society to make their preparations at once, and unite all their efforts to represent the French Photographic Society worthily at this Exhibition, to which the best productions of foreign artists will be admitted.

THE PATENT ALBUMENIZED PAPER.

SIR.—I was somewhat surprised to see, from your last weeks "News," that our talented friend Mr. Sutton is about to

patent a process for the preparation of caoutchouc-albumen paper, when, from what I can learn as to his method of preparation, the system has been in operation amongst many eminent photographers for four or five years at least, and I believe was invented by my old friend M. Gaumé of Mans, who obtained a prize from M. Le Duc de Luynes, through the Société Photographique de France in 1857 or 1858, I remember not which year. M. Gaumé prepared his paper in a solution of gutta-percha, or india-rubber and benzole, and sensitized it in a bath which contained alcohol. Again, M. Durer, of Paris, used india-rubber solution regularly, and I believe, uses it now. Herr Carl Sholts has used it for several years, I am informed, and M. Von Monkoven, I believe, published a formula for the use of it three years ago. I have used a solution of gutta-percha since 1858, both in Paris, in New York, and in Bremen Haben, and now use it in England; and should you think my formula worth the notice of your readers, I shall be happy to send you the details in the course of a few weeks, as I do not hold with those narrow-minded people who would patent for self-gratification that which of propriety belongs to the whole photographic profession. I admire Mr. Sutton, and give him all honour for his valuable works and suggestions; but I cannot help expressing my extreme surprise and regret that he should seek to monopolize to himself the honour to which M. Gaumé is entitled, and the profits which ought to be the common property of the profession. With many apologies for the length of my letter, and the indifferent English in which, as a foreigner, I am compelled to express myself, I remain, yours most respectfully,
ANGELO BIANCHI.

Art Studio, Zetten Hall, 22nd December, 1862.

[The use of waterproof solutions for preparing photographic paper is not new; but, until the publication of Mr. Sutton's specification, we cannot state the precise amount of novelty it may embrace. We remember repeated occasions on which such preparations have been proposed; but there are none, so far as we know, which are precisely the same as that of Mr. Sutton. M. Gaumé, for instance, used gutta-percha prior to albumenizing; others have used gutta-percha, india-rubber, &c., without albumenizing. Regarding the right to patent such things, it is a wide and difficult question. Whilst we desire to see the utmost liberality in everything connected with the art, and are convinced that much of its progress is due to the prevalence of this liberality, we cannot overlook the fact that there are occasions when it is due to the experimentalist that he derive some substantial profit from his labours. Few men have contributed more valuable suggestions, appliances, and improvements in the art of photography than Mr. Sutton—few with so much liberality. And of this we are assured, that he would not willingly appropriate either the credit or the profit due to others. If it should turn out that the idea has been so far forestalled as to make the patent of doubtful validity, we believe Mr. Sutton would be the first to propose that his process should be given freely to the public. We shall be glad to receive practical details, and the results of any analogous process, and give them the utmost publicity.—E.D.]

PAPER PREPARED WITH GUTTA PERCHA.

DEAR SIR,—Being a constant reader of your valuable publication, I have received great advantages from your remarks and suggestions. I have practised the art, as amateur, for the last ten years, and I found that the great desideratum is good paper, without that high gloss which is obtained on albumenized paper. In that direction I have for some time made experiments, which seemed to me satisfactory; but I still postpone to make it public until I shall have obtained the opinion of others. I have shown some prints to photographers in the neighbourhood, yet I intended to wait till fine weather. Reading your last number, I was taken by surprise to see that Mr. Sutton has taken a patent for albumenized paper, by rendering the paper waterproof. This is just the process that I pursued. He does it

with india-rubber. I discarded it, finding that I obtain better results with gutta-percha. Having rendered the paper waterproof, I iodized and excite. The two proofs which I enclose I have finished in a very short time. They print quickly. I have only washed them in several waters for the space of a quarter of an hour, that you may see if they undergo a change by light and moisture. You will kindly make some remarks about it in your next number, if space permits. I beg you to pardon this hurried note, having been in haste for the post. If you find the paper of any value, I will continue to experiment, and will send you, by your permission, specimens. I beg you also to remark if it will infringe Mr. Sutton's patent-right.—Yours respectfully,

ALEX. ARNSTEIN.

Ambleside, Dec. 22, 1862.

[Our correspondent is experimenting more especially in the direction of Mr. Cooper than Mr. Sutton. If we understand him rightly, he proposes the use of gutta-percha or india-rubber in place of albumen; Mr. Sutton as a preparation for albumen. The prints enclosed are very pleasing, and we shall be glad to hear further from our correspondent. We do not think he is trenching at all on Mr. Sutton's patent-right. See note to a preceding letter.—Ed.]

BROMIDES IN COLLODION.

DEAR SIR,—I beg to correct a few errors in my letter of the 26th of July, published in your issue of the 26th September, and 13th of October, 1862, just arrived.

Page 467, column 1: "But Mr. Blanchard's experiments appear to have," &c., should be, "appear at first sight to have," &c.

Page 467, column 2: "to solve the question of increase of sensitiveness," &c., &c., and a third portion, "with iodide of cadmium, 3 grains," &c., should be, "with iodide of cadmium, 3 to 4 grains," &c.

Page 479, column 1: "introducing cadmium as a component of the iodiser, &c., and that inferiority increased with the increase of cadmium," &c., should be, "and that superiority increased," &c.

I hope you will give me space to make some further remarks on the present subject, and to record in your journal also, in a comprehensive form, the manner of my experiments.

A.—Cadmium Iodized Collodion.

1stly, Superior in durability and sensitiveness, and equal in chemical intensity, under iron development, to the same with pyro.

2ndly, Whether under iron or pyro development, superior in durability, sensitiveness, and intensity, than bromo-iodised collodion developed with iron or pyro, the superiority being reciprocally as the quantity of bromide present in the bromo-iodide.

B.—Iodide of cadmium, 3 grains, iodide of ammonium, $1\frac{1}{2}$ grains, compared with iodide of cadmium, 3 to 4 grains, bromide of ammonium $1\frac{1}{2}$ to 2 grains, both under iron development. The simply iodized collodion, superior in every respect to the bromo-iodized, reciprocally as the quantity of bromide present in the latter.

C.—The same with cadmium and potassium, but with somewhat modified results and proportions; for in the case of the bromo-iodized, there is the usual limit to the introduction of bromide, when of the potassium salt.

D.—And in all cases of like combinations between cadmium and ammonium, or cadmium and potassium, whatever the proportions, provided that the cadmium salt did not fall below half the total quantity used, the simply iodized-collodion was:

1stly, Superior in every way under iron, to the same under pyro development.

2ndly, Under pyro, superior to the corresponding bromo; under iron only, when the amount of bromide was large.

3rdly, Under iron, superior to the corresponding bromo; under iron, reciprocally as the quantity of bromide present.

Thus, the collodion, iodized only with cadmium, under iron development, stands first; and iodized collodion, with not less than half of cadmium in it, and with iron development superior to itself when under pyro development.

All these experiments, be it remembered, were made with one collodion, with a bath very slightly acid with nitric acid; developers, pyro and proto-acetate of iron. They were all conducted as carefully as possible, and the results recorded are those obtained from each collodion in its best serviceable condition, and this, a little reflection will show, can only be done by repeated simultaneous trials of all the collodions on one and the same subject every two or three days, or every day (the latter the best plan), taking the best results of each up to its deterioration, and over the whole period of experiment (as the highest attainable excellence), for comparative tabulation.

Only this method could enable me to tell, or rather ascertain, which collodion stood the longest without deterioration, which gave the best detail, which the most vigorous in action, and which the most sensitive, &c.

And this now brings me to record the result of other experiments, not, like the last mentioned, exactly intended to show the comparative merits of iodides and bromides under iron or pyro development, but to define the quality of the salts best suited for any one sample of collodion which may be required for early use, or be available in its least serviceable condition within a given time.

A universal iodiser, or one suited for all collodions of reputable manufacture, is compoundable of equal portions of cadmium and ammonium, or cadmium and potassium, preferring the former combinations from its greater durability and power of conferring intensity. From this, as a standing point, it is not difficult to determine, by a few trials, in reducing one salt or the other, the iodiser best adapted for any collodions against the day of requirement, whenever that may be; and we can defer the day, or shorten the period of ripening, by the knowledge that we can confer keeping properties by increasing the proportion of cadmium, or injure them by the augmentation of ammonium. The first defers the age of ripeness or sensitiveness, but gives it greater duration; the second accelerates the said age, but makes it temporary—the more temporary when the ammonium is used as a bromide instead of an iodide.

And now, with this information, we may compare any number of collodions differently prepared and salted, whether only iodised or bromo-iodised, and determine the degree of their respective nature, properties of sensitiveness, durability, density &c., and cultivate any one or two, or all of these properties in the subsequent manufacture of other collodions, when intended to be particularly salted, which is probably the plan followed by most manufacturers.

If, however, with such different samples of collodion, salted so as to put them in the best serviceable condition against a certain day, comparative exceptions were made to determine the qualities of the salts employed, it would be an error, something similar to Mr. Blanchard's, for the result would not be a solution of the questions of iodides and bromides, but simply a comparison of the different degrees of sensitiveness &c., of several collodions particularly salted, when in their best serviceable conditions—a matter particularly of importance to those who manufacture collodion.

A sensitive plain collodion, with decided organic reaction, is, I think, well adopted for rapid work. By reason of those organic reactions, the decay of the collodion will be rapid; but it is a great help to rapid work to be able to extemporise, at a moment's notice, as it were, in quantities suitable for temporary requirements, instead of having several pints of cadmium collodion ripening on their shelves, and which may not be available in their best serviceable condition when most needed.

With such a collodion a large quantity of bromide is admissible. As intensity accompanies organic reaction, the bromide can be made a regulator of it, although the

duration of the reduction effected will vary with the energy of the organic reactions, eventually yielding to the latter, and to the re-establishment of the density, and its increase.

As I suppose such a collodion—because of its not keeping well in its plain state, but sensitive while it did keep—to be made up in small quantities, and salted with ammonium and cadmium, the most sensitive combinations I know of, which stands next to cadmium collodion; which admits of the free use of bromide, and which can be modified in sensitiveness, and in its effect upon the said collodion by the increase of one salt or the other, I am led to infer that some such case has made successful operators believe that the presence of the bromide in large quantities has played the important part of sensitiveness, when indeed it was rather attributable to the combination, including an alkaline salt, to the excitation caused, and to the collodion having been employed while that excitation lasted.

If, however, the bromide was the cause of it, any bromide should answer; and if the bromide was ammonium, it should be replaced by bromide cadmium, and a trial given. If the collodion were fit to be salted with iodide and bromide cadmium conjointly, the sensitiveness would be deferred appreciably, although more durable when reached. But if not of it, insensitiveness and destruction of the collodion would ensue, I do not say it would be impossible to make a collodion fit for salting with equal parts of iodide and bromide of cadmium; this would, however, be making a collodion to salt in a particular manner, and it cannot therefore effect the result of my experiments, establishing that bromide causes insensitiveness in proportion to its presence. For the different iodised and bromo-iodised collodions, from one sample, were used by me throughout their various states of sensitiveness, past their age of ripeness, and into their period of deterioration, and the best results of each recorded. Nevertheless, I say that wherever bromide can be introduced it is an advantage, as regards the reduction of excessive density, and in its capacity for faithfully rendering foliage, &c.

But that it is impossible to work rapidly without the use of large quantities of bromide, is, in my opinion, an error, the dissemination of which will cause, and has caused, many disappointments. The system of parading success, and attributing it to particular causes which are not the whole truth, is, to say the least of it, disingenuous. If the rapid operators, instead of attributing their success to the use of large quantities of bromide, were to explain how their collodion was made, the treatment it should receive, and its properties of keeping &c., and give a detailed method of working, it would then be the whole truth, and nothing but the truth. Until this is done, which no one need expect, it behoves us to accept their statements and proofs with much caution, especially when the results of careful experiments and extended experience are opposed to them. For in your own columns you have recommended infinitesimal doses of bromide, improperly ridiculed by Mr. Sutton, while many eminent photographers reject the salt altogether. To the mass of beginners, it is as well to point out that the use of large quantities of bromide, on which rapid operators claim their success, has, doubtless, some favourable conditions in the collodion for its presence, and in such case is a necessity of the particular method of working adopted—not the resuscitation, or successful application of a long neglected principle, applicable under every ordinary circumstance. In other words, the practice is not a radical photographic, but local necessity; and that, whenever followed without a perfect knowledge of the working of the rapid operator, disappointment and failure are always possible.

The next mail will arrive a fortnight hence, and I hope to read the commencement of the discussion on this bromide and iodide question, and eventually the decision which will be arrived at by wiser heads than mine.—I am, yours truly,

AUGUSTUS WEBB.

Photographic Notes and Queries.

TO SECURE CLOUDS IN LANDSCAPES.

SIR.—As the desire for securing natural clouds and proper atmospheric effects in landscapes is now happily increasing, I beg to acquaint you with a small instrument which I have lately been endeavouring to construct for facilitating this object, and would feel greatly obliged by your opinion as to its probable utility, through the medium of your answers to correspondents, as you will be, no doubt, better able to judge than I am. In the case of instantaneous views, or those taken over water, where the horizon is a straight line, I suppose an excess of exposure may be given to the foreground quite easily, by the ordinary flap shutter; but in the majority of landscapes, where a much longer period of exposure is requisite, and the horizon is seldom a straight line, the light cannot well be cut off from the sky by these means, without the more elevated portions of the foreground suffering from want of exposure.

The small instrument I have constructed, with the view of remedying this evil, consists of a folding hood placed on to the end of the lens-tubes, in front of the camera, and carrying in front a frame filled with a number of small slips, which fit into each other in such a manner as to form a light-proof covering, and admit of sliding up and down with a small amount of friction.

To use this the operator has simply to put his lenses in focus, and while he is looking at the image on the ground glass, to run his finger along the tops of these slips, and gently press them down till they form such an outline as to exactly cut off all the light from the sky; and then, when the foreground has had sufficient exposure, the frame is removed out of the way, and an instantaneous exposure given over all the plate, just sufficient for the sky and clouds.

The outline these pieces make is slightly serrated, but that assists in softening off the light more gradually.

The light may be still more gradually cut off, if need be, by gently lifting up the frame, or turning it round some time, during the exposure of the foreground. As the latter part of the afternoon is the only time when I can attend to photography, and as this neighbourhood is always enveloped in mist and smoke at this season, I have not had an opportunity of giving this contrivance a fair trial; but such trials as it has got lead me to think that only conditions favourable for photography are required for success. The enclosed, which I certainly cannot call pictures, were taken in the evening, and are sadly blemished by mist, smoke, and wind. The foreground was exposed about a hundred times as long as the clouds. The contrivance could be combined with the instantaneous shutter, so as to form one instrument.

It seems to me to make a considerable difference to the foreground, especially with a prolonged exposure and compound lens, as it cuts off in such cases all the light from the sky during the exposure of the foreground. This difference is most striking when the lenses are pointed towards the sun. Even in that case all sorts of haloes seem to be prevented. Perhaps, in cases where there are no clouds to take, it might be found useful for improving the foreground of the picture, and producing a sky of any desired density, to admit of painting in clouds—or in the case of dry plates.—I am, sir, your obedient servant,

Bruce Castle, 29th December, 1862.

ALPHA.

[If we remember rightly, the late Mr. Scott Archer was in the habit of using a method of securing a short exposure to the sky by a method similar in principle but different in detail. A piece of paper was torn or cut, with an edge following the outline of the horizon. This was fixed in a frame inside the camera, in such a way as to screen the sky during the greater part of the exposure, and turned down or removed for a few seconds at the close, so as to give a brief exposure to the sky. The object is so good that we hail every effort to facilitate it with pleasure. If there be one purpose we have more steadily kept before us than another, during the last few years, it has been to aid in the abolition of the unmeaning patch of white paper which has so long done duty as a sky in photographic landscapes, to the destruction alike of atmosphere, breadth, or real brilliancy. The two examples enclosed very satisfactorily illustrate that the contrivance of our correspondent will admirably facilitate the production of natural clouds in conjunction with a foreground requiring long exposure.—ED.]

Talk in the Studio.

DISTRIBUTION OF MEDALS.—It appears that the medals awarded by the jurors in the International Exhibition will be delivered to the proper claimants, on personal application, at the Exhibition building. The following letter has been forwarded to medallists:—

Exhibition Building, South Kensington, W., Dec., 1862.

SIR.—I am directed by her Majesty's Commissioners to inform you that the medal which was awarded to you by the International jury will be delivered on presentation of this letter at the Jury Offices, Western Dome, any day before the 10th of January, between the hours of ten a.m. and four p.m. If you cannot yourself conveniently attend, any person whom you appoint to act on your behalf may receive the medal for you on presenting this letter, countersigned by you. This letter must be produced to ensure admission to the building at the Western Dome, Prince Albert Road, and will have to be left with Mr. Iselin, the secretary of the juries, as an acknowledgement of the medal having been delivered. The certificates of honourable mention will not be ready for delivery till a somewhat later day.—I am, &c.,

(Signed)

F. R. SANDFORD.

PHOTOGRAPHY AND THE LANCASHIRE FUND.—We have pleasure in stating that Mr. Meagher, Camera Maker, of Coppice Row, has forwarded to the Photographic Exhibition a very handsome and large trunk camera, which formed a chief attraction in his case at the International Exhibition. The price of the camera is £25, and he has requested the Secretary of the Society to devote the proceeds, when sold, to the fund for the relief of our distressed countrymen in Lancashire.

"PHOTOGRAPHY IN ITS APPLICATION TO THE MAGIC LANTERN EDUCATIONALLY CONSIDERED."—This is the correct title of the paper to be read by Mr. Samuel Highley, F.G.S., &c., at the meeting of the Photographic Society, on Tuesday evening next, at King's College.

M. ASSER'S PROCESS OF PHOTOLITHOGRAPHY.—We have been favoured by Mr. Toovey, of the firm of Simonon et Toovey, lithographers, of Brussels, with some very fine examples of M. Asser's process of photolithography. These for half-tone, far transcend anything of the kind we have before seen. Several architectural subjects are very fine, and one of a portion of the Town Hall, in Brussels, which was quite untouched, leaves little indeed to be desired. It is full of detail, with every gradation of half-tone down to the deep pure black of the shadows. In general effect it is strikingly suggestive of a drawing by Prout. There are also copies from oil painting, and life size head from a statue, with quite sufficient half-tone for the subject, and is wonderfully bold and fine in drawing. An excellent effect is produced in some by printing in, with a separate tint, a sketchy suggestive sky; in others there are the graduated tints from warm brown to the blue sky, which gives to some Egyptian scenes from rather hard negatives an exceedingly fine effect. M. Asser adheres in the main to the formula described in his specification. For reproductions starch and abichromate are used, for negatives from nature, requiring the preservation of half-tone, a paste of wheaten flour with bichromite is used. It is probable that some specimens will be exhibited at the forthcoming exhibition of the Photographic Society.

To Correspondents.

CORNISH CLOUGH.—You will find information on the subject of magic lanterns in many of our back numbers, we may especially mention Nos. 84, 87, 88, 89, 90, 126, 127, and others. Perhaps 126 will answer your purpose best. Photographic slides and other apparatus for the lantern you may doubtless procure of Bland and Co., Horne and Thornthwaite, Murray and Heath, Cox, Samuel Highley, and others.

VAISSIER ET VÉREY.—We have enquired of Mr. Fry as to his yellow glass, and have received confirmation of our remarks last week. The dealer happened to have a sample of yellow glass, which proved non-actinic; but has not been able to supply with certainty subsequent applications for the same article.

T. M. LEAHY.—In speaking of paper prepared with the resin of silver, Mr. Cooper means, as you conjecture, paper prepared with the resin, without chloride, and then floated on the silver solution. We have been much interested in your experiments with ammonia. The ALMANAC was sent.

HAYFORDWEST.—Benzole will dissolve a coating of india-rubber from glass. Probably boiling water and friction will make it peel off. 2. So far as our own experience is concerned we prefer the tannin and honey dry plates to any others; except, perhaps, the collodio-albumen, and they are more

troublesome to prepare. Perhaps the best mode of washing is that practised by our American correspondent. He uses six dipping baths, removing the plate from one to another, after remaining long enough in each for the coating, &c., of another plate. Sufficient washing to prevent stains is thus secured without much trouble. 3. There may be some danger of unequal sensitiveness in Mr. Keene's method, but we cannot say with certainty, as we have not yet had the opportunity of trying. We are glad to hear you find the NEWS so useful, and thank you for the additional subscribers you have secured for us.

JAMES STODDARD.—Where Mr. Warner has not given a formula, he is doubtless referring to that already given by Mr. Cooper, on page 537, Vol. VI., of the PHOTOGRAPHIC NEWS, which stands thus:

Pure frankincense	10 grains
Mastic	8 "
Chloride of calcium	15 "
Spirit	1 ounce.

We do not understand Mr. Warner as proposing any new proportions, but describing the method of manipulating, which in his hands has been successful.

AMICUS.—Mr. Osborne's papers on photolithography appear in Nos. 214 and 221 of the PHOTOGRAPHIC NEWS, pages 481 and 570 of Vol. VI. A notice of Col. James' system of photopyrography appears on page 164 of the same volume, or No. 187. It is based on the same principle as photozincography and photolithography, but the transfer itself is used to print from instead of putting it on stone or zinc.

J. SCRITA.—The streaky background arising from a new bath we have generally found to disappear on neutralizing, sunning, and adding sufficient acid. Sometimes the presence of actinic light in the dark room will cause such streaks. We have known such streaks disappear after using the bath a short time; and sometimes we have found the addition of a little tincture of iodine to the collodion sufficient to remove them. Moving the plate laterally whilst in the bath, will sometimes prove a remedy; and sometimes changing the position of the plate, immersing it cross-wise when about half-excited in the vertical position. Try these remedies, and use the bath a little. It is a pity to put the bath aside as useless when it is working so well in other respects.

A LADY AMATEUR.—You will find full instructions for recovering the silver from hypo baths, &c., on page 50 of our fifth volume, or No. 126. Any gold remaining in old toning baths may be precipitated as dark powder by adding solution of proto-sulphate of iron, the quantity or strength is unimportant, so long as you add until no more precipitate is thrown down. The brown powder may be converted into chloride of gold by dissolving in *aqua regia*.

C. P. W. states that on his albumenized paper, excited on a 100-grain silver bath (ammonia-nitrate, or rather oxide of silver dissolved in nitrate of ammonia) when hung up, the silver solution collects in drops as if repelled by the paper. We have never met with such a difficulty, and cannot well understand it; possibly the paper has not been floated sufficiently long to form the proper combination; possibly too much nitric acid has been added to the bath. Possibly the paper is defective in some way, or has been handled and become greasy.

C. F. W.—We have no means whatever of knowing whether the advertisement in question is *bona fide* or not. 2. So far as we can ascertain, the lenses of the maker referred to are very variable, some good and some bad. We prefer the last-mentioned as being most trustworthy. 3. Portraits can be taken with a view lens, but it is not the best instrument for such work.

C. W. S.—You will be able to obtain all information of Mr. Alfred Harman, 3, Albert Cottages, Hill Street, Peckham, the Secretary. The next meeting is held at the City of London College, Leadenhall Street, on the evening of Thursday January 8th, when, if you choose, you can attend. We shall have pleasure in proposing you.

D. WESTON.—We are not sufficiently familiar with the lenses of any of the makers you name to speak with certainty of their qualities, or advise you satisfactorily. We believe the first mentioned permits buyers to test the lenses, an arrangement which ought to lead to satisfactory results. Whether the others do so or not we do not know.

T. A NEW SUBSCRIBER.—We regret that we cannot charge the back numbers at a reduced price. Many of them we will willingly pay full price for ourselves. The figures are accidentally omitted, you will find them, however, half a dozen lines above. 2. The printing process used by Mr. Fontaine in his printing-machine is that by development. The paper is prepared with an iodide and bromide, and a condensing lens is used to concentrate the light. By these means instantaneous or very rapid printing is not impossible.

J. H.—The enlarged prints from America, exhibited at the meeting to which you refer, were printed on ammonia nitrate paper. We were not present ourselves, and did not see them, but we learn from trustworthy authority, that they were very poor indeed. We have not yet heard particulars of Mr. Stuart's new apparatus, but the prints he has already produced by the old one, are, as nearly as possible, perfect.

NOTICE.—A good glass positive cannot be converted into a good negative. If it be good as a positive, it will be insufficiently exposed for a negative. Negatives may be produced by means of iron only, but not always so conveniently as with pyrogallic acid intensifying. A collodion, giving a somewhat dense image, developed with acetate of iron, is frequently sufficiently dense, without further intensifying. Varnishing is only necessary for the protection of the negative. If it have been well washed, and the exciter paper be quite dry, no danger arises from the two surfaces coming into contact. If the paper be damp, however, a brown stain may result, especially if the slightest trace of hypo remain in the film. Varnishing is always safer, but where one or two prints only are required, it may be dispensed with.

A PRINTER.—If clouds are well painted at the back of the negative, or if they be well printed in separately, we think they are quite permissible. We have often said that in such subjects success is the touchstone of legitimacy. It is only when the thing is badly done that it challenges criticism. The object is to produce really good pictures; this done, the means will not often be challenged.

Several correspondents in our next.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to the Office, 32, PATERNOSTER ROW, LONDON.

THE PHOTOGRAPHIC NEWS.

Vol. VII. No. 227.—January 9, 1863.

PHOTOZINCOGRAPHY.*

THE work of Col. James and Captain Scott, on photozincography, is one of the most interesting books which have been published in connection with the art, not simply as a complete and detailed statement of the processes and formulæ used at Southampton, but for the variety of fine reproductions in printer's ink with which it is illustrated.

Referring to the latter first, we are enabled to endorse the opening remark in Col. James's introduction, as to the high state of perfection to which these processes have been brought at Southampton. For reproduction of engravings and similar subjects, we have before said, that both the process of Col. James and that of Mr. Osborne have reached a pitch of excellence which leaves little to attain or desire. Amongst the dozen photographic illustrations given in this book are exquisite copies of engravings, some of which have a great deal of fine, close work, which is most perfectly rendered. We may mention amongst these a reduced copy of a fine engraving from a painting by Raffaele; two of Piranesi's engravings of antique vases of rare design; and a reduced copy of one of Volpato's engravings of a panel in the Vatican, painted by Raffaele. There are also fine specimens of hill shading, and fine detail in maps; a reduced copy of an indenture; a page of Domesday Book; and a page of the folio edition of Shakespeare of 1623. Each of these are perfect illustrations of the value of the art for the several kinds of work represented.

The technical details of the work will be read with much interest and attention amongst photographers. The processes are divided for clearness into three parts. These consist in the production of the negative; the preparation of the positive photographic print in greasy ink; and the transference of the print to the surface of the zinc, or to stone, and the preparation of that surface for printing. These processes are here more fully described than in any previous work, and a brief *résumé* will doubtless be interesting to our readers.

It must always be borne in mind, that the negative most suitable for giving good results on the lithographic stone, is one perfectly dense in the whites of the picture, and quite clear and transparent in the blacks; in short, great brilliancy, intensity, and freedom from any trace of foggy deposit on the shadows, and as in engravings, maps, &c., the gradation is secured by the artificial means of lines, hatching, or stippling, the gradation known by photographers as half tone, is not required in the pictures.

The collodion used is simply iodized, and is preferred about a fortnight old. The formula given stands as follows:—

Pyroxyline	80 grains
Iodide of cadmium	15 "
Iodide of potassium	75 "
Alcohol sp. gr. 812	10 ounces
Ether sp. gr. 725	10 "

The usual silver bath of from 35 to 40 grains to the ounce of water is used, slightly acid with nitric acid, in preference to acetic acid.

* On Photozincography and other photographic processes employed at the Ordnance Survey Office, Southampton. By Captain A. De C. Scott, R.E., and the direction of Col. Sir Henry James, R.E., F.R.S., &c. London: Longman & Co.

The development is effected by iron. The formula stands thus:—

Protosulphate of Iron	1 ounce
Glacial Acetic Acid	6 drachms
Alcohol	6 "
Distilled Water	1 pint.

The image is sufficiently developed by means of this solution, especial care being taken to stop its action before there is the slightest trace of deposit on the fine lines or shadows. Further intensity is then secured by the application, after fixing, of pyrogallic acid, a grain and a half to the ounce, twenty-four minims of acetic acid, and a few drops of a solution of silver. If further intensity be required the negative is immersed in a weak solution of bichloride of mercury until its surface is whitened; it is then treated with a weak solution of hydrosulphate of ammonia, which gives the required density. To prevent lateral deposit filling up the fine lines, the last process of intensifying is effected after the plate has been suffered to dry, the edges being varnished to prevent the film slipping.

The apparatus used for convenient copying was fully described in the PHOTOGRAPHIC NEWS, Vol. III., and we do not find that any material alteration has been made except in the adoption of Dallmeyer's triple achromatic lens for copying.

To produce the transfer the paper must be hard, thin, and tough, of even texture, and free from woolliness, and but slightly sized. Paper made from linen is most suitable; the best results have been obtained with the ordinary bank post paper, slightly sized. The proportions of the bichromate and gelatine—gum has long been abandoned—vary with circumstances. It is necessary that the solution of gelatine be fluid at a temperature of 100°, and that the proportion of bichromate be sufficient to render the whole of the gelatine insoluble under the action of light, but no more. The quantities here stated are two ounces and a half of bichromate of potash dissolved in ten ounces of hot water, added to three ounces of gelatine, dissolved in forty ounces of hot water. The fluidity is maintained by placing the dish containing the mixture in another containing hot water. The paper is floated for a few minutes, and when dried, the process is repeated. When again dry it is passed through a copper-plate press, on a hot steel plate.

The time of exposure to the negative varies, from one minute in the sun, to twenty minutes in dull light. When sufficiently exposed, the blacks appear of a brownish green.

The transfer ink, is made as follows:—two pounds of chalk lithographic ink, and one pound of middle linseed oil varnish are ground together; four ounces of Burgundy pitch are melted in an iron vessel, and to it are added two ounces of palm oil, and two ounces of white wax; these are well stirred together on the fire until they begin to burn. The ink and varnish, first mixed, are then added, and the whole thoroughly incorporated.

For use, a portion of this is thinned with turpentine to the consistency of thick treacle. To apply this ink to the surface of the print, a zinc plate or lithographic stone is inked in the usual method with a roller; the bichromate print is then laid face down, and passed through a lithographic press. By this means the whole of the surface is covered with a uniform surface of ink.

To remove the ink from every part but the image, the print is floated for five minutes on water at 90° Fah. back

downwards. It is then laid on a porcelain slab, and the surface rubbed gently with a soft sponge dipped in gum water. This will remove the unaltered gelatine, and, if all the other operations have been rightly performed, a perfect positive image in printer's ink remains. This, when dry, is ready for transferring to zinc or stone.

The zinc plate is, of course, prepared to receive the transfer; this is effected by first smoothing it, and then giving it a grain by means of fine sand and muller. The surface so produced has an affinity for the greasy ink somewhat similar to that of the lithographic stone. To effect the transfer the print is placed for a minute or two between two sheets of damp paper, and then laid on the prepared zinc plate, and passed through the lithographic press. This done the print is moistened on the back, which causes the ink to leave it the more readily. On removing the transfer paper, the image is left in the transfer ink on the zinc plate. It is now etched, as the next process is termed, by means of a mixture of gum-water, phosphoric acid, and a decoction of galls. Four ounces of Aleppo galls are steeped in three quarts of water for a day, and then boiled. One quart of this is added to three quarts of gum-water about the consistency of cream, and three ounces of a solution of phosphoric acid. To prepare the latter, some sticks of phosphorous are placed in a pint bottle, not quite full of water; a hole is made through the cork to admit air; this acting on the phosphorous, which projects above the water, produces oxidization, and the water dissolves the phosphoric acid as soon as it is formed, and in a few days produces a solution strong enough for use. The etching liquid is poured on the plate, and allowed to remain from twenty seconds to a minute, fine work requiring a shorter time than coarse work. The plate is then washed with water, and dried.

The transfer ink is next removed from the plate with turpentine, or with a mixture of turpentine, olive oil and gum water. It is then rolled up with printing ink, and is then ready for use.

In the process which Col. James has termed *Photopapyrography*, the image obtained in greasy ink, on paper prepared with gelatine and bichromate, instead of being transferred to zinc or stone, is used to produce one or more positive impressions on paper, by passing it through the lithographic press. The negative should be in such cases reversed, either by being taken through the glass plate, or by means of a reversing mirror or prism.

For the reproduction of manuscripts, printed matter, &c., the use of negatives obtained, by wet collodion on paper instead of glass is recommended. The sensitiveness is stated to be superior to that of wet collodion on glass; and when waxed it yields excellent results. With such negatives the image need not be reversed for photopapyrography, as there will be but an inconsiderable loss of sharpness in printing through the paper.

The volume contains an interesting account of the rise and progress of the application of photography to this branch of the public service, and of the discovery of photozincography. It is unnecessary to revive any discussion on the subject here. Different steps in the discovery were probably due to different individuals in the establishment, who have, from time to time, received due acknowledgment. The general control, the suggestion, direction, or permission, have rested with Colonel James, and photozincography very naturally receives public recognition as his process.

Since the publication of this book, Colonel James, as our readers know, has devoted some attention to the production of half-tone, an accident having suggested the means, in a certain condition of the prepared paper, produced by keeping it a few days before use. The several specimens, with which Colonel James has favoured us of the results, have been full of promise. There is unquestionably abundance of half-tone, the fault at present existing being rather a want of deep blacks for the shadows, or a want, perhaps, of perfect gradation generally. Sufficient is, however, already produced to indicate the possibility of obtaining

photolithographs with proper gradation of half-tone, pure lights, and deep shadows. This possibility has frequently been doubted, on the ground that gradation in lithography could only be obtained by artificial or conventional means. We find enough done to convince us that more may be done, and we have pleasure in learning that Colonel James is prosecuting his experiments in this direction.

We have before stated, that by far the best photolithographs we have seen, as regards gradation of tone, are some done by Asser's process. In these, instead of gelatine or albumen, a paste of wheaten flour is used with the bichromate. The precise condition of the organic matter in combination with the bichromate, seems materially to affect the question of half-tone, and suggests a direction for experiment. A specimen we received from Col. James, produced by the bitumen process, which has recently been vaunted as giving half-tone, was a lamentable illustration of the worthlessness of that method, as the print is almost entirely destitute of any qualities which could give it value, and strikingly enforces the fact, that the process is entirely superseded by the method of transferring now in successful use.

PHOTOGRAPHIC CHEMICALS:

THEIR MANUFACTURE, ADULTERATION, AND ANALYSIS.

Alumina Salts.—The salts of alumina are only of indirect interest to the photographer; we shall, therefore, give but a brief sketch of their history. The earth itself is a white powder, tasteless and inodorous, and after ignition insoluble in most acids. It may readily be prepared in the hydrated state, by adding an excess of ammonia to hydrochlorate or nitrate of alumina, and thoroughly washing and drying the gelatinous precipitate. If alum is used, the resulting hydrate is contaminated with sulphuric acid. Alumina has less affinity for acids than any of the bases we have yet mentioned, and forms with them compounds which have little stability. They are decomposed sometimes by simple ebullition, and deposit hydrate of alumina. When the earth is precipitated, either in this manner or by the addition of an alkali, it has a remarkable tendency to carry down with it organic, and especially colouring matter, which may be in solution; many kinds of inorganic impurity, commonly classed under the generic term mud, or dirt, are also carried down and removed from solutions in this way. This property of alumina is applied to great use in the arts and manufactures. The colour-maker utilizes it in the preparation of lakes, by precipitating alumina in the presence of some brilliant organic dye; and it is frequently used also for the purpose of decolorising solutions. Recently precipitated alumina has a similar property. When put into a liquid containing organic colouring matter, it almost invariably attracts this to itself, becoming tinted with the particular colour, whilst the solution is rendered almost colourless. The dyer and calico printer avail themselves largely of this property. When cotton goods are placed in a solution of a colouring matter, they refuse to fix the substance, and do not take the colour in the same way as silk or woollen goods would. The manufacturer, therefore, employs the artifice of precipitating alumina into the cotton fabric before immersing it in the colouring solution. Upon now dipping it into the coloured bath, the alumina, acting as a mordant, causes the goods to take the dye readily.

Chloride of Aluminium.—This salt has recently become of considerable commercial importance, being the starting point in the preparations of the metal aluminium. It is, like many other chemical compounds, very difficult and tedious to make on a small scale, although attended with no difficulty when prepared as a manufacturing operation. When alumina is dissolved in hydrochloric acid, it may be assumed that the solution contains chloride of aluminium; but upon evaporating the liquid to obtain this body in the solid state, a residue is left containing chloride of aluminium with the elements of water; and upon further increasing the

heat, the water is decomposed, its hydrogen uniting with the chlorine to form hydrochloric acid, which goes off, and its oxygen uniting with the aluminium to form a residue of alumina. It is not possible to avoid this decomposition, except by setting to work in a somewhat round-about way. An intimate mixture of alumina and carbon is prepared by thoroughly incorporating together alumina, powdered charcoal, sugar, and oil, to the consistence of a thick paste. This is introduced into a crucible, and heated, out of contact with the air, to redness. The sugar and oil are in this manner decomposed, and the carbon of their composition is left in a state of intimate mixture with the alumina and powdered charcoal. The mass is introduced warm into strong porcelain or glass retorts, through which a slow current of perfectly dry chlorine gas is allowed to pass. When all the air has been swept from the apparatus, heat is applied to the carbonized mass, when the alumina is decomposed by virtue of the double chemical persuasion to which it is subjected: the carbon takes the oxygen from the alumina, forming carbonic oxide, whilst the chlorine unites with the aluminium to form chloride of aluminium. This is carried along by the carbonic oxide gas, and condenses principally in the form of a fine powder, and partly as a solid mass at the extremity of the neck of the retort, which must be very large, or it will be stopped up by it. The alumina must be precipitated from a solution which contains no sulphuric acid, as otherwise the alumina will carry some of this down with it, and will give rise to the formation of chloride of sulphur, which will mix with the chloride of aluminium. Chloride of aluminium forms a lemon-coloured waxy mass, transparent, and of a crystalline texture resembling talc. It fuses when in large masses, a small quantity immediately evaporating on the application of heat; it boils at about 360° Fah., and fumes slightly in the air, smelling of hydrochloric acid. It rapidly deliquesces in the air, forming transparent drops, and dissolves in water with a hissing noise and evolution of heat. In this state it has fixed to itself the elements of water which cannot be driven off again by heat, the compound splitting up, as we have above described, into hydrochloric acid and alumina. When the anhydrous chloride of aluminium is heated with potassium or sodium (the latter method is always employed at the present time), metallic aluminium is separated from it with formation of chloride of potassium or of sodium. If the aqueous solution of chloride of aluminium, or the liquid obtained by saturating hydrochloric acid with hydrate of alumina, is allowed to evaporate in a warm and very dry atmosphere, crystals are deposited, which are very deliquescent, and very soluble in alcohol. They contain twelve atoms of water of crystallisation, and 43.96 per cent. of chlorine. This salt has not been much used in photography; but since chlorides which are very soluble in alcohol are not very common, it is likely that chloride of aluminium could be employed for several useful purposes, especially in the collodion process.

Nitrate of Alumina.—This is a very deliquescent salt, formed by saturating nitric acid with hydrate of alumina. Upon evaporating the solution carefully down to a syrupy consistency, and allowing it to stand in a cool dry place, the nitrate crystallises out in thin colourless laminae. It has been successfully applied, like nitrate of magnesia, for the preservation of sensitive collodion plates.

Sulphate of Alumina and Ammonia, or Ammonia-alum, as it is generally called.—This is the most important salt of alumina, and is prepared by hundred of tons at a time. Alum shale is boiled out in dilute sulphuric acid, and the solution is mixed with sulphate of ammonia derived from the gas residues. The solution is boiled down rapidly, and the salt is deposited in the form of a fine white crystalline powder, known by the name of alum meal. This is rinsed from the impure mother-liquor by a small quantity of water, then dissolved in hot water, and allowed to crystallise in large wooden tubs, capable of holding some tons' weight at a time. After the magnificent display of alum which our

readers have recently seen at South Kensington, no detailed account of the appearance of this body is needed. Although called alum, this name strictly speaking, belongs to potash alum, a compound exactly similar to the one we have now been describing, but containing potash instead of ammonia. Until within the last few years, potash alum was always made. It was found, however, that ammonia, which would confer equally good crystallising powers upon the alumina salt, could be obtained in almost unlimited quantities from the gas-purifying liquors; and it has, therefore, so completely replaced potash alum, that it is a difficult matter to obtain even a small specimen of the latter compound.

PHOTOGRAPHY AND THE HEALING ART.

[We are desirous of giving especial prominence to the appeal of Dr. Wright to photographers. No more interesting or important application of photography can be made than that which makes it an adjunct to the art of healing. A collection of good photographs of all kinds of medical and surgical cases, placed in the library of the Medical and Chirurgical Society of London, cannot fail to be of the utmost value in aiding the study of such cases. We feel sure that any of our readers possessing negatives, prints from which will add to the completeness of the collection, will gladly respond to the appeal of their brother photographer, our friend Dr. Wright.]

SIR,—Physicians and surgeons desirous of retaining lasting representations of important cases (on the accuracy of which might depend decisions as to life and death in similar cases occurring to others) were formerly compelled to resort to the pencil of the artist. But the reliable talent available for such a purpose was not readily procured, and when obtained involved a large expense. The photographic art supplies a simple and cheap method of perpetuating the appearance presented by any particular form of diseased structure at any stage of its progress, or of its cure, and medical men are daily more and more availing themselves of the opportunities thus presented. It took hours to make an exact sketch where now it requires only as many seconds, and the presentment of that seen is not only accurate in every detail, but gives facilities for such comparative measurements as the hand following the eye would never have obtained. Hence it follows that photography has been of vast service in this department of its working, and there is scarcely a professional photographer who has not been called on, at some time or other, to picture the appearances produced by deformity or disease, or to perpetuate some triumph of surgical skill. Such records are of lasting value; they do not tell merely of that which they represent; they also afford assistance, such as no verbal description could supply to those who may be in doubt when similar cases occur. Hence it well may happen that the exact verisimilitude which a photograph affords will determine doubts on which the issues of life and death may depend.

Photography is, *par excellence*, an art of exactitude, it neither exaggerates, or mitigates what the eye of the camera sees, and therefore is practically reliable even where so much depends on its evidence. The importance of the photographic representations of professional subjects has led the Medical and Chirurgical Society of London to determine on adding to their extensive library a collection of photographs of subjects of professional interest.

As a Fellow of the Medical Chirurgical Society, and a Member of the Council of the Photographic Society, I have willingly undertaken to gather and arrange the contributions. In the hands of professional and amateur photographers in various parts of the kingdom are numerous negatives, for the most part taken at the request of medical men. I believe, that considering the object in view in making this collection, I am justified in asking your readers

to supply me with prints from any such negatives in their possession—of course unmounted—with a few words of reference to the case so photographed, or to the medical practitioner for whom it was taken.—I remain, yours obediently,
H. G. WINGRUP, M.D.

23, Somerset Street, Portman Square.

Critical Notices.

THE PHOTOGRAPHIC NEWS ALMANAC; or the YEAR-BOOK OF PHOTOGRAPHY for 1863. London: PHOTOGRAPHIC NEWS OFFICE, 32, Paternoster Row.

FOR very obvious reasons, our notice of the YEAR-BOOK OF PHOTOGRAPHY for 1863 must be confined to a simple description or statement of its purpose and character.

In the ALMANAC for the present year we have aimed at greater comprehensiveness than on former occasions. We have in each year's issue endeavoured to give, in addition to the various memoranda likely to be interesting in a Photographic Year-Book, a *résumé* of the definite discoveries of the past year. But this is by no means an accurate or complete register of the advancement of the art; much of the most valuable progress consists in improvements arising out of the cumulative experience of able men, by steps so gradual, that they cannot easily be defined and set down. A record of such improvements is, nevertheless, of the utmost interest and importance to the student striving after perfection, and we have, therefore, availed ourselves of the facilities we possess of becoming familiar with the practice of the ablest photographers of the day. Guided by the information thus gained, and our own experience, we have given a re-statement of the most important processes, embodying all minor improvements, as they are successfully adopted by the best men of our time. It will be seen that our YEAR-BOOK thus becomes, not simply a collection of scraps or memoranda, but a manual of improved practice for general reference.

A simple statement of the principal contents will, perhaps, be the most satisfactory notice. Of course, there is the calendar, and usual general information of an almanac. The days of meeting, exhibitions, and officers of the various societies are given. A briefly detailed statement of the annals of photography for the past year follows. Then, under the head of Photographic Processes and Formulae, a complete statement of the wet collodion process, including the manufacture of collodion; the preparation of the silver bath; development and developing solutions; modes of intensifying, &c., &c. A chapter follows, containing a brief statement of authenticated formulae communicated by various first-rate photographers; amongst whom we may name T. R. Williams, Southwell Brothers, H. P. Robinson, and others. A chapter on the construction of glass-rooms and lighting the sitter will be found useful. A chapter on instantaneous photography contains a communication on the subject written by Mr. Blanchard for the work. Methods of printing, toning, and fixing follow, with chapters on printing on silk, on resinized paper, on double or fancy printing, &c.; chapters on mounting, on glass positives, on portraiture and card pictures, on enlarging negatives, on the solar camera, &c., follow. The department assigned to "Processes and Formulae," is completed by a series of short chapters devoted to the Dry Collodion Processes, containing the Collodio-albumen Process as practised by Mr. Mudd; the Tannin Process; the Tannin and Honey Process; the Fothergill Process; Dry Collodion without Preservative; a Valuable Preservative Process; Instantaneous Dry Plate Photography; and Modes of Developing Dry Plates.

The "New or Modified Processes" of 1862, are then briefly stated; amongst these will be found: a New Alkaline Dry Process; the Morphine Dry Process; a Carbon Process; Improved Iron Developer; Photography in Natural Colours; Alcolene, or Collodion without Ether; a New Photographic Varnish; Mode of Preventing the Discolouration of the

Nitrate Bath; Formic Acid in the Developer; Mr. Sutton's Rapid Dry Process; Mr. Keene's Rapid Dry Process; Photography on Gelatine; Fumes of Ammonia in Printing; &c., &c. A variety of useful tables, a recapitulation of new apparatus, &c., a list of photographic patents during the year, the New Copyright Act, with instructions for the registration of photographs, and some other matters complete the work, the whole constituting, as we think our readers will agree with us, a very comprehensive photographic *vade mecum*. The YEAR BOOK contains something like twenty pages of matter more than on former editions, but the price remains as formerly, one shilling.

THE COLLODION PROCESSES, WET AND DRY. By THOMAS SUTTON, B.A. London: SAMSON LOW & SON.

FEW men have the art of explaining themselves more simply, and writing more directly to the purpose, than Mr. Sutton, and, as few men have a better knowledge of photography, he could not fail to produce a good book on the subject, and one which every photographer should read.

The work before us contains a very complete and lucid statement of the wet collodion process, from the manufacture of the pyroxyline to the varnishing of the negative; a general description of the dry processes, and details of the tannin process, the collodio-albumen process, and the rapid dry process, recently published by the author; together with chapters on instantaneous photography, positive printing, chemicals, apparatus, &c. Each of the subjects is treated with a simplicity, and freedom from ambiguity, which is quite refreshing, and in the best possible style for an instruction book. The chapter on the manufacture of pyroxyline, is an especially valuable one, giving a clear idea of the principles involved, and describing formulæ which, worked with anything like care and attention, will yield an excellent soluble cotton, without risk of failure.

We like Mr. Sutton best in his description of manipulation, &c., there he is unsurpassed in the happy homely simplicity, and graphic force of his style. On some points of theory and practice, as our readers know, we do not agree with him. Although with modified force, he still depreciates the value of the bromides in wet collodion, regarding them only as the succedaneum for pure chemicals and good manipulation. In the dry processes generally, however, the importance of a large proportion of bromide is enforced, as essential to rapidity. We cannot entirely agree with him in his unqualified condemnation of commercial collodions advertised, as being "improved by age." Most photographers are familiar with the fact, that some collodions, especially if iodized with cadmium, do improve or ripen with keeping. The term "unchangeable," as applied to collodion, is probably untenable, as that implies stability for an unlimited period. We have in our possession however, collodion, we made three years ago, which we shall employ as a standard, by which to test other samples, and we rarely find any excel it in sensitiveness, whilst in cleanness and brilliancy it is rarely rivalled. The principle of manufacturing collodion and other preparations by published formulæ, to enable intelligent photographers to understand with what they are working and what reactions they may expect, which Mr. Sutton is enforcing when condemning the said advertised collodions, is one which cannot be strongly commended, and we believe that the manufacturer would in no case be a loser by such publication. We had marked some portions for extract, but the pressure on our space forbids their use at present; we shall probably give them on some subsequent occasion. In the meantime we commend the work to all our readers.

HARMONIOUS COLOURING AS APPLIED TO PHOTOGRAPHY. By an ARTIST-PHOTOGRAPHER. Fourth Edition. London: James Newman, Soho Square.

THE fact that four large editions of this work have been called for in four years, is a strong argument for the excel-

lence of the book, and the appreciation in which it is held by photographers. It is also a satisfactory illustration of the fact that photographers generally are interested in a work which, besides containing technical instructions in the art of applying pigments, is also full of hints on the application of art principles to photography, for we can scarcely suppose that there are many thousands of professional or amateur colourists, or that all who have bought the book, have done so simply for the purpose of learning to colour.

The new edition contains, not only full instructions for every mode of colouring photographs, but a very lucid statement of the general principles of harmonious colouring, and of the application of those principles to photography. Fresh chapters are added on the retouching in crayons of enlarged pictures, and also in colouring such pictures in pastel. A very useful chapter, containing "A Few Words on Portraiture," ought to be read by every photographer, and especially by those engaged in the production of card pictures.

COMPOSITION AND PROPERTIES OF GUN COTTON.

BY AUG. TESTELIN.

PYROXYLINE does not appear to be a chemical combination, in definite proportions, of cellulose with the oxygenic elements of nitrogen; it appears to us too variable in its composition and most essential properties, not to appear rather a physical modification, effected by condensation more or less considerable and perfect of a nitrogenous gas, which appears to be the protoxide of nitrogen.

In our opinion, the capillary fibres of the ligneous substance operating upon these gaseous elements by an attractive action comparable, in some measure, to the catalytic force of the cellular interstices of carbon, platinum, sponge, and many other bodies, which present this peculiar property of condensing certain gaseous bodies, without in any way uniting with them, and permitting the disengagement of these gases by the action of influencing causes more or less energetic.

Cotton, after undergoing the operations which transform it into pyroxyline, undergoes no change in its physical properties; still, in the generality of cases, it becomes less soft to the touch, and appears considerably disaggregated. But a remarkable phenomenon presents itself in this product, which is, that it has assumed an extremely singular passive condition, which renders it unattackable by chemical agents as powerful as concentrated sulphuric acid, nitric acid, potassa, and most other substances which completely destroy organic matters.

These different properties appear to us to be due to the fixation of a considerable quantity of protoxide of nitrogen in the organic cells, which exercise, like all capillary interstices, a powerful influence upon certain gases, which they condense and solidify, becoming at the same time inaccessible to the influence of other bodies, with regard to which the modified substance becomes less attackable, and then establishes itself in a truly passive state, by a cause analogous, so to speak, to that which produces a similar phenomenon upon iron and other bodies.

But when a more intimate cause comes to penetrate these spaces of the ligneous matter to destroy their cells, and dilate the gas which their attractive power concentrates, then the latter, spontaneously resuming their primitive normal state, *i.e.*, an infinitely larger volume—by breaking the cells which still form an obstacle, and the provocative force acting only upon a point—the vigorous action resulting produces an enormous disengagement of heat, propagating itself in every direction with an extreme energy; the organic matter is burned in contact with protoxide of nitrogen, a burning gas *par excellence*—the carbonic acid, spontaneously produced and dilated by heat, joins its expansion to that of the other gases from whence results a vivid explosion.

The cellulose transformed into pyroxyline acquires the

property of dissolving in a mixture of ether and alcohol; it appears, nevertheless, that it is not a true solution so produced, but simply a separation of the ligneous particles, and, according to M. Davanne, a swelling of the fibres analogous to the swelling of the granules of starch, or of fish isinglass in water.

For, upon precipitating a solution of pyroxyline in ether and alcohol by water, we easily recognize the distinct remains of the organic tissue in the deposit formed, composed of elongated fibres which have preserved the principal properties of the nitrated cotton; that is to say, they can be redissolved, partially it is true, in the ethereal mixture, and be instantly decomposed, after drying, upon contact with a burning substance only: the material then fuses, on account of its compactness, the same as gunpowder when pulverized and compressed.

This apparent solubility of pyroxyline in alcoholic ether, is therefore simply only the effect of a disaggregation of the fibres of the ligneous substance, but not of the compound cells of the organic body.

The cells not being destroyed by the dissolving vehicle, and so remaining quite entire in the liquid, it is natural that they should preserve their principal properties in continuing to exercise their condensing action upon the nitrogenous gas, until an influencing cause, such as heat or light, comes to provoke the more or less partial disengagement of the condensed gas, which is then liberated slowly, by reason of the little energy of the cause, and various other circumstances, favourable or unfavourable, amid which the phenomenon takes place. The protoxide of nitrogen, thus disengaged, combines with the elements of the solvent itself, changing it by forming more hyponitric acid, which concurs powerfully to the rapid destruction of all these substances. Whatever be the care employed in the preparation of nitrated cotton, after it is dried it instantly disengages a small portion of the protoxide of azote it contains, of which the oxygen of the atmosphere determines the conversion into hyponitric acid, which is always found in large quantities in bottles in which gun cotton has been kept.

When the vessel containing the gun cotton is hermetically closed, and the disengagement of the gas is very little favoured by any external influence, the hyponitric acid formed, withdraws the water from the ligneous matter and partially decomposes it; nitric acid is also formed ultimately, the action of which upon the pyroxyline and the organic portion of the substance, disengages the oxygenic elements of the nitrogen, and ends by causing a more complete destruction. A portion of the mass becomes liquid under the prolonged action of the nitric acid, and is converted into a substance similar to xyloidine, which the water precipitates from its solution, and there remains in the liquid other matters, soluble and deliquescent, arising from a more advanced decomposition; for these phenomena are slow to be produced, so that several different compounds must be developed in succession.

Nitric acid does not form a true combination with cellulose, hence a product, the elements of which are in definite proportions, cannot result; and it is the diversity of these proportions which gives rise to the variety of pyroxylines, which may always be seen among the specimens arising from different manufactures.

It is generally admitted that there are four varieties of pyroxyline, because analysis has sometimes afforded, according to the species, 2, 3, 4, or 5, equivalents of a nitrogenous gas, which is considered to be hyponitric acid, but which is also oxygenized, finally only by the modifications it undergoes during the reactions effected by the decomposition of the organic matter.

Moreover, these numbers, which are taken to represent the equivalents of the composition of the fulminating matter, are rather only the two extremes, in some respects, that are most frequently found, and between which there may be an infinity of varied proportions. We are sustained in this supposition by the diversity of proportions found by every

author who has attempted its direct analysis, and from which, finally, we have only been able to deduce general averages, the summary of a great number of experiments.

This, however, is easily understood, when we know that these varieties of pyroxyline are constantly mixed in the specimens obtained, no matter what the method of fabrication has been; it is therefore only the dominant species which constitute the properties, more or less characteristic, of the whole. But these species do not really exist, and why we admit them, as we have before stated, is, the varied and in determined proportions according to which is produced the absorption of the gas in the capillary interstices of the fibres of the ligneous matter.—*Bulletin Belge de la Photographie*.

Upon the preceding the editor of *La Lumière*; M. Gaudin, remarks:—"I readily admit, with M. Testelin, that nitrated cotton is not constantly in definite proportion. The action of nitric acid upon the cotton differs constantly with the proportion of water it contains, to such a degree, that in the preparation of a single tuft, we may be certain that the proportion first imbibed differs in nature from the portion last imbibed, in consequence of the accumulation of water in the acid, which has already acted, remaining, for I have proved, by a decisive experiment, that the reaction is instantaneous. It is also certain that the nitrated cotton is unstable by nature; with time it undergoes a kind of fermentation, which sometimes causes it to explode, and it is this which forms an insurmountable obstacle to its employment as a substitute for gunpowder. Witness the catastrophe at Bouchet, where some thousand kilogrammes exploded spontaneously, scattering the building in which it was contained to dust, and even hollowing the earth beneath it, like a funnel. Photographic cotton is less explosive, nevertheless from time to time it causes serious accidents; and quite recently, the explosion of some kilogrammes demolished the laboratory of M. Mathieu Plessis.

"But to conclude that the instability of the product is due to the absence of combination, appears to be an error, when we consider the known properties of photographic cotton, it *dissolves*, in fact, in alcoholic ether. I underline the word, to express that it is a true solution rather than a simple suspension. In fact, photographic collodion constitutes a *perfectly transparent* liquid—a quality which never attaches to a body held in suspension, if held, as supposed. Upon slowly evaporating it on an impervious surface, it detaches itself in limpid glassy pellicles, which also preclude the presence of any detached body. Finally, the filtering of collodion through paper, which succeeds very well, abundantly proves that the cells, if cells there be, cannot exceed the hundredth part of a millimètre in diameter, and this absolutely excludes any idea of ligneous fibre. Soluble photographic cotton, therefore, constitutes a true combination of lignine with certain oxygenised products of nitrogen; but there exists also a series of these products which differ from each other by insensible degrees, from whence results the difficulty of constantly obtaining the same product, when following, as nearly as possible, the same conditions of fabrication."

TO SECURE CLOUDS IN LANDSCAPES.

BY W. U. WARNER.

In the NEWS of this week, I read, under the above heading, a (to me) somewhat complicated arrangement for the securing of the very beautiful effects of cloudland. Having, in the course of my professional engagements, been often compelled to resort to various "dodges" to effect the best results in the securing of such effects, and knowing that simplicity in apparatus is at all times desirable, I will proceed to give you my little contrivance, which was arrived at by a puff of wind having one day blown over my camera.

The lens I was working with, was Dallmeyer's No. 1 triplet, to which was attached his flap shutter, made, as you know in mahogany.

My view consisted of a very white parsonage-house, with a

lawn in front cut up into beds, containing a large quantity of green leaves of various shades; behind the house were some very picturesque clouds, which I was desirous of obtaining. The size of the picture was 10 by 6.

Having focussed, I proceeded, as usual, to prepare the plate, when a sudden squall arose, and the catastrophe occurred as mentioned above, whereby the flap and sides of the shutter were broken. Then the following idea suggested itself, which has since been perfected by Mr. Robert Murray of Murray and Heath, viz., to make one side of the shutter a little broader than the other, and in the place of wood to have metal sides and flap; then to ascertain the exact angle at which the lower line of the shade divides the whiter portion of the picture from the darker, marking this by a lead pencil line on the broad side of the shutter. On exposure, proceed thus:—open the flap at first 1-16th of an inch within that line, holding the brass knob by which the flap is raised in your hand, according to the exposure you wish to give the foreground; at the same time move the shutter upwards and downwards, in a rapid movement, four or five times during the exposure of the foreground, say half an inch above the line marked on the side of the shutter in order to soften the light into the dark, and thus avoid an abrupt line; then for a moment close the shutter; next open the whole for one or two seconds, as the case may be, to give the clouds.

The same principle may be applied to the taking of street views, where you require an absence of people and perfect delineation of buildings. Having lately—in fact, at the beginning of last month—been requested to take a view of the Ross Corn Exchange, for the purpose of engraving, and its situation being in the main street, with people constantly passing and repassing, I found that to get a satisfactory picture it would be necessary, in the foggy frosty weather we then had, to give an exposure of two or three minutes. This, you see by the specimen sent, was done, the only figure being the one placed there in order to give the comparative height of the building. All this has taken much time to explain, the actual operation taking only a few seconds to effect.

THE URANIUM DEVELOPER.

Mr. J. R. Wood, writing to the *American Journal of Photography*, says:—"I saw it stated in the PHOTOGRAPHIC NEWS that Dr. Van Monckhoven was experimenting on developers, and that he had found protosulphate of uranium to develop collodion pictures with less exposure than protosulphate of iron. Wishing to try that salt for that purpose, and having some of the sesquinitrate of uranium by me, I converted it into the protosulphate by the following simple means:

If a solution of sesquinitrate of uranium in water be heated with clean iron filings, decomposition soon takes place, precipitating the protoxide of uranium, which mostly adheres firmly to the excess of iron filings. If these be washed and then mixed with a warm dilute solution of sulphuric acid, the precipitated uranium rapidly dissolves, forming a dark green solution, which requires filtering. This solution, mixed with an excess of sulphuric acid, I have used as a developer, and believe it to require less exposure than the sulphate of iron with acetic acid. Perhaps some of your readers might try it, and report."

TO PUT A PAPER POSITIVE INTO A LOOKING GLASS.—A correspondent sends us the following, which may interest some of our readers. Having cut out the picture, take a quarter plate glass, well cleaned, lay a sheet of tin foil on two or three thicknesses of cloth or paper, and spread some quicksilver with a piece of cotton wool. Next, attach the portrait with varnish, to the glass. All being ready, lay a sheet of clean paper on the top of the quicksilver, and place the glass, with portrait attached, on the sheet of paper. Now press hard, and draw out the sheet of paper gently. The quicksilver will run round the edge of the portrait, making a beautiful looking-glass, with a portrait in the centre, giving an effect, something like a daguerreotype.

SPIRIT PHOTOGRAPHS.

In making some further extracts from these extraordinary narratives, we may suggest the singular resemblance between the images described and the phantoms which sometimes appear as the result of imperfectly cleaned plates, on which pictures have before been produced. It will be noticed that only a portion of the figure is generally visible; that it has a shadowy indefinite appearance; and that it is often accompanied by fog and stains; which, in the narrative, are described as "cloudy vapours," "white undefined masses," "blurs," &c. The image, too, is often of a different size to the sitter, as though it is suggested "the spirit were at a different distance from the camera;" no allusion being made, however, to the trifling difficulty in regard to focus, which must follow. It is probable that the idea has had its origin in the reappearance during development of the imperfectly-removed image of a former picture, and this has been received by some credulous persons as a spiritual manifestation. That which originated in delusion is probably maintained by imposture, by a variety of possible means. The identification of the images as portraits of deceased friends, is only explainable by remembering that such barefaced impostors as Joe Smith, the Mormon Prophet, found thousands of followers, and that the wildest delusions have never been wanting in "respectable evidence" and unhesitating believers.

These are not the fitting pages for entering into any discussion of the claims of spiritualism, as it is termed, but we are somewhat concerned in protesting against our art being made the auxiliary either to delusion or imposture. The *Spiritual Magazine* remarks:—

"Those who are so carefully making their investigations are not ignorant of the manner in which the well-known stereoscopic ghosts are produced, of which the invention, like that of the stereoscope itself, is claimed, and we hope more honestly than the latter, by Sir David Brewster. These ghost imitations are produced by having a figure dressed to represent the unearthly visitor, and standing in position during just half the time required for the full operation, then moving away, giving the objects behind it the other half, to impress their image faintly on the negative plate."

"Dr. Gardner, in his address to the Boston Spiritual Conference, says:—'To me there is no cause for doubt. The pictures themselves furnish evidence in their gauze-like appearance, that has not been imitated. Careful examination will show the counterfeits that have been made to be essentially different. I do not doubt that Mr. Mumler is a peculiar medium, and has an organization and magnetism adapted to the production of these spirit photographs.'

"In the *Banner of Light*, of the 29th November, is also contained an elaborate review and description of the process and its results, from which we make the following extracts:—

"They are ordinary *cartes de visite*, but with a faint additional figure, not defined by a distinct sharp outline, but vapoury and semi-indefinite. The whole of the figure is not displayed, usually, only the head and bust.

"The first is a portrait of the medium, W. H. Mumler, with one hand on a chair, the other holding the black cloth covering just taken from the camera. In the chair sits a half-defined female form, apparently about twelve or fourteen years old. This was at once recognized as a deceased female relative. A cloudy vapour hovers about the head of this spirit—an effect we never before saw in any sun picture. One we have seen has a faint disc of light about the head, as if luminous rays were shooting outward, but all stop at a determined circular outline. Two others have a similar effect, but the circle would be sufficiently large to enclose the whole figure, if the card were of greater dimensions.

"The second picture taken by this medium has the spirit of a lady sitting on a chair, with a white undefined mass of something behind her, like two or three pillows. The features are quite sunken, with a serious expression. We are told this is a likeness of the spirit sister of Mr. J. J. Ewer, as she looked when wasted by consumption. The father of the deceased fully recognizes the likeness, as do the rest of the family.

"The next is an elderly lady leaning on a chair, in which

sits a faintly-defined form of a young man playing upon a guitar. This figure is shown more fully than the last, one leg being visible to below the knee, the other not being visible at all—looks as if moved, leaving only a blur. This was at once recognized as a deceased brother, who made guitars and was fond of playing upon them.

"Another is a female figure leaning upon a chair, the hands placed together, and eyes elevated as in prayer. The spirit appears of a larger size, the face and bust only visible. The face is elevated, as if in prayer.

"Another is a gentleman sitting, with the edge of a white marble table near him. The spirit is behind him, and a little smaller—a female figure, with the hair dressed quite plain and Quakerish, a small white collar about the neck, tied with a dark ribbon, a close fitting dress, visible only to the waist.

"A gentleman from Illinois sat for his portrait, and raised the right hand as if holding something. He was told that was a very unbecoming attitude, but he said, "No matter; take it so." When the plate was developed, there sat upon the raised arm a child, leaning its head upon the sitter's shoulder. This child is not very clearly defined; it appears a little larger than in nature, as if nearer the camera than the arm it sits upon. The dress is transparent, with the hand and arm of the sitter seen through it.

"Here is another, an elderly lady, in a dark dress, standing by a chair. The spirit of her deceased husband is with her, a man evidently older; the figure about the size of the lady. A standing collar is visible on one side, the other turned down; black neck-stock, white shirt bosom. The other portion of the costume is not distinctly defined. This is Isaac Rabbitt, inventor of the celebrated Rabbitt metal. The lady referred to above is Mrs. Rabbitt, the wife of the deceased, who assures us that the picture represents her husband as he appeared in his last illness, and she pronounces it, unequivocally, a good likeness, and *knows* that she has not been deceived by the artist.

"The next is a portrait of Mr. Luther Parks, an elderly gentleman, well known in this city, sitting with his hat on. The spirit in this picture is entirely unlike any of the others. It is a female figure floating in the air, the hair combed back over the head, a loose-fitting dress with short loose sleeves gathered in at the elbow; a bracelet on the left fore arm, which is extended, with a wreath of flowers in the hand, toward the gentleman. The right hand is pressed against the side, and over the head (not on it) floats a wreath of flowers. This spirit is quite transparent, the folds of a curtain being distinctly seen through the whole of it.

"Dr. William B. White has two photographs taken at the same time; one (a lady) in front, and another behind a chair. These spirits, he says, have been with him many years. He is a clairvoyant, and sees the spirits and talks with them. They told him, eight years ago, that the time would come when a group, sitting at a table, would have their photographs and those of their spirit-friends taken together. Still further; that they would be taken in colours.

"The last we shall notice, at this time, is that of a gentleman of commanding figure, noble bearing, and dignified demeanour, well known, particularly to express agents in the business community, who stands by a chair, in which sits the form of a young man reading a book. Another picture of the same gentleman has the dim form of Daniel Webster near him. The statesman is recognized at a glance, and bears a close resemblance to portraits painted in the latter portion of his lifetime—the sunken cheeks particularly. The top of the head is bald, with the hair combed up from each side. The expression of the features is very grave and solemn. The dress is not distinct, but, so far as it can be perceived, is unlike anything in the painted or engraved portraits, but slightly resembles the costume on the Washington statue, in the State House; nearly half the figure is displayed, and is a little larger than the mortal, as if nearer the instrument. It is quite transparent, the chair being quite distinct behind it.

"The spirit of Webster purports to be frequently with this gentleman, manifesting its presence whenever a suitable medium is available. This gentleman has received from Webster a private signal, by which he says he is able to identify its presence, and, therefore, that he is not liable to be imposed upon by any other spirit. While in position for this picture, he experienced the usual signal, thus adding another proof of identity."

"Dr. A. B. Child, of Boston, says—

"Mr. Mumler invited me to bring my own glass on which

to make the picture; to examine the camera, its tubes, and lenses; his chemicals; to see him apply the collodion to the glass, and immerse it in the silver bath; to see him take it out of the bath and put it in the shield, then in the camera, and then to go with him into the dark closet, lighted only by a little lamp, and see him take the glass from the shield, which is a little dark box, then pour on an iron preparation, wash it under a stream of water, and then hold it to the little lamp, and see the picture of a mortal and a spirit on it. In compliance with this invitation, I carefully observed all the above operations in detail.

"Mr. Mumler asks for any fair investigation that shall convince the people that his claims are just and genuine. This is right, and as it should be. And it is not unjust or ungenerous, in a new thing—so great and so beautiful as this, if true, must be for the people—to ask the privilege to *prove* it true beyond the shadow of a doubt."

"And in a letter written a week after, and after further investigation, Dr. Child says:—'The best and oldest photographic artists in Boston are unanimous in declaring that they know of no means by which these pictures can be produced, as Mr. Mumler produces them.'

"Mr. Joseph B. Hall, of Portland, Maine, writes to the *Banner of Light* an account of his experience, which appears to contain a good test. He says:—'I was permitted to go into the "dark room" with the operator, and I saw another figure, beside my own, developed upon the plate. Being unable to wait for the picture, I came home, and, a few days after, copies were sent to me. At first, although the face of the spirit-figure was familiar, I did not recognize it, as I confess I was looking for some one of my relatives; but soon I recognized the countenance of a young friend of mine, who died in Augusta, Me., some three or four years since. He was not in my mind when I sat for the picture, and I had hardly thought of him for months. Immediately I forwarded one of the pictures to the friends of the young man at Augusta, *without* intimating to them that I had recognized it. Yesterday I received a letter from his sister, from which I make the following extract:—

"I received the photograph, and it was my brother F.—. The likeness nearly overcame me, it was so plain. His collar and cravat are precisely as he used to wear them. It is as plain a picture to me as the one hanging in my room. We all see it alike, and I think any one who knew him must see the likeness at once. It was a great surprise to me, for I never dreamed of seeing any of our friends on your picture; I hope, however, that the test will make up for the disappointment to you. I do not think these pictures *flatter*, but this is a true likeness.

"Augusta, Me., November 16, 1862."

"The point has been raised by one of the New York papers, and Judge Edmonds has written the following letter, which puts the question on its true basis:—

"To the Editors of the *Evening Post*.

"Your article of yesterday in regard to spiritual photography professes to solve the mystery, and announces that Appleton's artist can do the same thing, wherever there is a photograph of the dead person.

"That is not the mystery of this thing. But it is to take a picture containing a likeness of a person who is dead, and of whom there is no photograph or likeness in existence!

"This is what the Boston operator professes to do, and the question is, "Is that so?" J. W. EDMONDS."

We echo the question of Judge Edmonds—"Is that so?"

The International Exhibition.

REPORT OF THE JURY ON PHOTOGRAPHY AND PHOTOGRAPHIC APPARATUS.*

PROGRESS SINCE 1851.—THE PRINTING COMMITTEE.

To the discovery of the collodion process, no doubt, may be attributed the immense impetus which was now given to the art. Daguerreotypes had been taken by Beard as early as the year 1843, he having patented for England that process which the generosity of the French Government had thrown open to the world by awarding a pension of 10,000 francs for the discovery—4,000 to Daguerre, and 4,000 to Niecepe. Claudet and Mayall, with some half dozen others, comprised all the professional photographers in 1852, who supplied the photographic wants of the public. After another five years there were in the metropolis alone above 150 establishments for the taking of photographic portraits; and, again, at the present time, the "London Directory" tells us that there has been a vast increase.

* Continued from p. 3.

This must still comprise but a very small portion of those who obtain their living by the sun's rays. Scarcely a favourable spot for the practice of the art is left untenanted; and we were lately informed that, for a desirable house in Regent Street, an enterprising and wealthy firm had given nearly double the former rent obtained for the premises. Every country town of note, and even some remote villages, now possess one or more practical photographers. Travelling photographic vans also throng the rural districts; and a statement of the consumption of photographic requisites seems to be quite fabulous.

A paragraph lately appeared in the daily papers stating that one firm alone, in London, used upwards of half a million of eggs annually, to obtain albumen for the formation of positive printing paper.

Beyond the discovery of Mr. Archer, two other causes, especially, have conduced to the spread of the photographic art in England—the formation of the photographic societies of London and Edinburgh, together with other local societies, and the removal of the patent restrictions which threatened the earlier practisers.

In April, 1852, Mr. Roger Fenton issued, as honorary secretary, a proposal to establish a photographic society, in which it is stated that, since the Exhibition of 1851 the science of photography had advanced at a more rapid rate than in preceding years. At the Exhibition of 1851, the lovers and students of the art in all parts of England were brought into more immediate and frequent communication. Ideas of theory, and methods of practice, were interchanged; the pleasure and the instruction were mutual. In order that this temporary state might become permanent, it was proposed to unite in a common society, with fixed places of meeting and a regular organization, "all those gentlemen whose tastes have led them to a cultivation of this branch of natural science;" but, still, a degree of doubt seemed to exist as to the strength of the infant art, for it is suggested that it is needful to ascertain the amount of support such a proposal is likely to obtain, by those desirous of uniting to send their names, with suggestions for its success, to the gentleman who had so kindly undertaken to suggest it and act as the first secretary.

The proposed formation of the Photographic Society, no doubt, influenced the second result, for Sir Charles Eastlake, the President of the Royal Academy, had been in constant communication with photographers, in their previous councils, accepting the office of first president of the proposed society, he, in conjunction, with Lord Rosse, addressed a letter to Mr. Fox Talbot, which, together with Mr. Fox Talbot's reply, appeared in the *Times* newspaper of August 13th, 1852, and, as they are both important in the progress of the history of the art, it is desirable that they should be here recorded.

I.

London, July, 1852.

DEAR SIR,—In addressing to you this letter, we believe that we speak the sentiments of many persons eminent for their love of science and art.

"The art of photography upon paper, of which you are the inventor, has arrived at such a degree of perfection that it must soon become of national importance; and we are anxious that, as the art itself originated in England, it should also receive its further perfection and development in this country. At present, however, although England continues to take the lead in some branches of the art, yet, in others, the French are unquestionably making more rapid progress than we are. It is very desirable that we should not be left behind by the nations of the Continent in the improvements and development of a purely British invention; and, as you are the possessor of a patent right which will continue for some years, and which may, perhaps, be renewed, we beg to call your attention to the subject, and to inquire, whether it may not be possible for you to obviate most of the difficulties which now appear to hinder the progress of the art in England.

"Many of the finest applications of the invention will probably require the co-operation of men of science and skilful artists. But it is evident the more freely they can use the resources of the art, the more it is that their efforts will be attended with eminent success.

"As we feel no doubt that some judicious alterations would give great satisfaction, and be the means of rapidly improving this beautiful art, we beg to make this friendly communication to you in the full confidence that you will receive it in the same spirit—the improvement of art and science being our common object.

ROSSE.

C. L. EASTLAKE.

"To H. FOX TALBOT, Esq., F.R.S."

II.

Lacock Abbey, July 30, 1852.

"MY DEAR LORD ROSSE,—I have had the honour of receiving a letter from yourself and Sir Charles Eastlake respecting my photographic invention, to which I have now the pleasure of replying.

"Ever since the Great Exhibition I have felt that a new era has commenced for photography, as it has for so many other useful arts and inventions. Thousands of persons have now become acquainted with the art, and from having seen such beautiful specimens of it produced both in England and in France, have naturally felt a wish to practise it themselves. A variety of new applications of it have been imagined, and doubtless many more remain to be discovered. I am unable to pursue all these numerous branches of the invention in a manner that can even attempt to do justice to them; and moreover, I believe it to be no longer necessary, for the art has now taken a firm root both in England and France, and may be safely left to take its natural development. I am as desirous as any one of the lovers of science and art whose wishes you have kindly undertaken to represent, that our country should continue to take the lead in this newly discovered branch of the fine arts; and after much consideration, I think that the best thing that I can do, and most likely to stimulate to further improvements in photography will be to invite the emulation and competition of our artists and amateurs by relaxing the patent right which I possess in this invention. I therefore beg to reply to your kind letter by offering the Patent, with the exception of the single point hereinafter mentioned, as a free present to the public, together with any other improvements in the same art, one of which has been very recently granted to me, and has still thirteen years unexpired.

"The exception to which I refer, and which I am desirous of still keeping in the hands of my own licensees, is the application of the invention to taking photographic portraits for sale to the public.

"This is a branch of the art which must necessarily be in comparatively few hands, because it requires a house to be built or altered on purpose, having an apartment lighted by a skylight, otherwise the portraits cannot be taken indoors, generally speaking, without great difficulty.

"With this exception then I present my invention to the country, and trust that it may realize our hopes of its future utility.—Believe me to remain, my dear Lord Rosse, your obliged and faithful servant,

"H. F. TALBOT.

To the EARL OF ROSSE, *Connaught Place, London.*"

On the 22nd December, 1852, the first public exhibition of photographs was opened by the Society of Arts, in their rooms in the Adelphi, and a large number of pictures, principally by the paper processes, were displayed. On the 20th January, 1853, a meeting of photographers took place in the rooms of the Society of Arts, and the Photographic Society was established. Sir C. L. Eastlake, President of the Royal Academy, became the first president of the new society. This society has become the parent of a numerous progeny of other societies, which have since sprung up largely in all parts of the kingdom.

The concessions made by Mr. Fox Talbot, in the foregoing letter, did not satisfy photographers, who felt that the "single point" reserved was that which hindered the practice more than all the others conceded. Accordingly, the art was daily becoming more practised and lucrative to the promoters, when Mr. Fox Talbot, in December, 1854, brought an action against Mr. La Roche, a photographic artist, to restrain him from taking collodion portraits. After a trial lasting two days, before Lord Chief Justice Jervis, a verdict was returned adverse to Mr. Talbot's claim, since which the art, freed from patent restrictions, has progressed with an uninterrupted flow of success.

The early experimentalists in the collodion process confined their efforts mainly to the production of positives on glass, and little thought was originally given to the securing of negatives by that process. On the discovery, however, that the collodion image was suited for use as a negative from which positives on paper might be printed, and that results much superior in delicacy and perfectness of definition, with greater rapidity of exposure were thus obtained, the attention of photographers was chiefly directed to this process. The delicacy of detail which was possessed by the collodion and albumen negatives was found to demand a finer surface for its perfect rendering than that usually possessed by even the finest photographic papers; to meet this difficulty it was proposed to apply to the paper a coating of albumen. One of the earliest records that we find of this application is in a communication by Mr. H. Pollock, addressed to the *Journal of the Photographic Society*, in July 1853. The process has since become general, and is almost universally practised; although the glaze thus given to the surface is not entirely satisfactory in an artistic sense, yet the facility it affords for rendering delicate definition in a class of pictures, the perfect and minute detail of which is an especial beauty, will always be a strong inducement to continue its use.

It is unnecessary here to refer at length to the calotype and waxed-paper processes and their progress since the Exhibition of 1851; they have been, for a variety of reasons, to a large extent superseded by the collodion process. The waxed-paper process has received a variety of modifications, and is still practised with success by some photographers, especially in tropical climates. An allusion cannot, however, be made to these methods without expressing some regret that the calotype process, the oldest method of producing photographic pictures, and one by which many of the most beautiful productions of the art have been obtained, possessing many advantages peculiarly its own, should have fallen so largely into disuse.

A new difficulty soon developed itself, and the want of permanency in photographic prints was forced upon the attention of all interested in the progress of the art.

One of the first to call attention to this falling, and to the importance of devising some means to give greater stability, was the Patron of the Photographic Society, His Royal Highness the late Prince Consort; at his suggestion a committee was formed for the examination of the causes upon which the fading of positive prints depend, and if possible to suggest methods for the securing of permanency.

In May 1855, a committee, consisting of Mr. Delamotte, Mr. Hardwich, Dr. Percy, Mr. Henry Pollock, Mr. Shadbolt, and Dr. Diamond, was appointed by the Photographic Society for this purpose; His Royal Highness the Prince Consort contributing the sum of £50 towards the expenses of the inquiry. The special objects of the committee were thus stated:—

1st. To report upon the evidence that can be collected with regard to photographs that have been printed for a long time; to ascertain whether there are any that appear to be quite unaltered by time, and, wherever it is practicable, to find out the methods by which they were prepared.

2nd. To conduct a series of experiments carefully, preparing photographs by different means, and exposing them under various circumstances, in order to ascertain what method combines in the highest degree the essential qualities of permanency and beauty.

(To be continued.)

Proceedings of Societies.

LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting was held in the theatre at King's College, Mr. FRANCIS BEDFORD in the chair.

The minutes of a previous meeting were read and confirmed. The SECRETARY then read a letter just received from Lieut.-General Knollys, in reply to a communication from the secretary, in which he stated that His Royal Highness the Prince of Wales would have pleasure in becoming the patron of the society.

The CHAIRMAN called attention to a couple of prints from an enlarged negative, by Mr. W. H. Warner. One was on albumenized paper, the other on resinized paper; the latter possessing more softness and detail than the other, but being a little cold in tone. He also called attention to a series of photolithographs, by Messrs. Simonau and Toovey, of Brussels, produced by M. Asser's process, sent by Mr. G. Wharton Simpson. A couple of rolling presses, by Mr. Wadly, of Sheffield, were also exhib-

ited, and the Chairman explained that Mr. Waddy was present, and would answer any questions regarding them.

The following gentlemen were elected members of the society: Messrs. W. Stouchose, E. Fox, P. Meagher, W. E. Debenham, J. Rivington, and Sir A. H. K. Macdonald.

Mr. S. HIGHLEY then proceeded to read a paper "On Photography in its Relation to the Magic Lantern, Educationally Considered." A variety of mechanical adaptations were shown during the course of the evening, and at the close of the paper an interesting series of transparencies, photographed from nature, and from engravings, were exhibited by means of the magic lantern and the oxyhydrogen light. Amongst these were a variety of fine microscopic objects, a series of transparencies from Kaulbach's illustrations to "Reynard the Fox;" some from Shaw's Bible illustrations; others from Hogarth's engravings; some of Mr. England's Parisian street scenes, and American scenery, and a variety of miscellaneous subjects.

At the termination of the illustrations, the Chairman stated that it was necessary that two auditors should be elected to examine the accounts, against the annual meeting to be held next month. M. Heisch and M. Chaudet, jun., were proposed and elected, and after a vote of thanks to Mr. Highley the proceedings terminated.

Correspondence.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 7th January, 1863.

M. E. BAROUX, a wood engraver, has claimed the merit of having solved the problem of photography on wood, inasmuch as by a simple process he obtains the design on wood, *not reversed*, with every delicacy of light, shade, and detail. The wood is not attacked by the sensitive preparations, and if the proof happens to be unsatisfactory, it can be immediately removed by passing a wet sponge over it. The block can then be recovered with the sensitive coating, and a fresh proof taken. The blocks retain their usual hardness and solidity, and are cut with as much facility as blocks unprepared. The sensitive coating is so thin that it offers no impediment to the graver, while it readily receives corrections, or retouching, with the ordinary black lead pencil. M. Baroux has not yet communicated his process, but I name it in order to stimulate your readers to a satisfactory solution of this important problem.

An apparatus for operating with in the open air has lately been introduced by M. Rousseau de la Farge: it permits of working with wet collodion, of sensitizing the plate, and of completely finishing the proof, in full sunshine.

This portable apparatus does not require the ordinary objective to be changed; it serves rather as an auxiliary to it, as they can be united together.

It is composed of a grooved box to carry the glass plates, behind which is a compartment for the bottles. To this box there are adapted two vertical baths, by suitable hooks and fastenings. The upper portion of the baths has a groove equal in size to the thickness of the principal slide, of which more hereafter, and intended to receive it during the operation. To keep it fixed, they are furnished with two stop-plates projecting a little over the opening. The rabbet of each bath is closed on one side, and can be on the other by an india-rubber spring. The opening of each bath is closed by a cover coated with gum-elastic. Pressure is exercised and maintained by two screws.

The nitrate of silver bath must be made of an impermeable substance, which has no action upon the solution, such as glass or gutta-percha; and it must be enclosed in a wooden case. The developing bath, of orange-yellow glass, must be protected in a similar manner. If it be composed of any other impermeable material, it must have two plates of yellow glass fixed parallel to its two sides, and carefully cemented to avoid leakage. The slide holding the plates during exposure in the camera opens at its lower part, and is closed at will by means of a slip of whalebone, wood, or

india-rubber sticking in a groove, and in another external one, having its corresponding sides parallel, and at the same height on the other side.

In this slide there is a second, which plays within the first, and is intended to receive the collodion plate; it is called the *plunger*, because it serves to introduce the plate into the baths by plunging into it. It is formed of bands of copper or of brass, of the same breadth and thickness, soldered together. This slide must be properly silvered. It is moved from the principal slide into the baths, and from the baths into the principal slide, by a cat-gut string passing to the outside by a hole through the upper part of the principal slide.

This plunger may be made of vulcanized india-rubber. A spring, of a particular form adapted to the outside shutter of the slide, permits of a suitable pressure being exercised at will upon the plate placed within the slide.

The manipulations with this apparatus are extremely easy to perform. We commence by placing the principal slide containing the plunger upon the nitrate of silver bath; the slide passes to the opening of the bath, and is stopped by the partition of the bottom at the point of complete coincidence of its opening with that of the bath. We next open the shutter of the slide, and collodion the plate, which is placed in the plunger. Then the shutter is closed, taking care that its spring be properly adjusted; then the stop-plate is withdrawn, and the plate falls into the bath. After it has become sufficiently sensitized, it is returned to the principal slide by pulling up the cord on the outside. The opening of the principal slide is now closed by returning the stop-plate to its original position, the bolt of the springs withdrawn, and then the plate is ready for exposure in the camera. To develop the image obtained, the slide is carried to the bath of protosulphate of iron, and operated with as described. For the sensitizing bath, with this difference, however, that the bath is turned on its hinges so as to examine the development of the image by transparency; the principal slide may then be withdrawn from over the bath on leaving the plunger, which is withdrawn afterwards, so as to avoid staining the principal slide. It now only remains to wash and fix the picture. If necessary, other baths may be established between those mentioned above and the box carrying the glass plates.

Before commencing another picture, the slide must be cleansed of all traces of the iron developing solution. For the movements of the plunger to be perfectly free, the internal space of the principal slide must be narrower than the bath, and the lower opening of the principal slide must be rounded at the edges, and bevelled.

The plunger can be dispensed with by employing silver pincers and a screw, to seize the plate at its upper end. We can also employ different hooks. In this new system the plate moves in grooves formed by the shutters of the slide, and two fillets fixed upon the interior surface of the shutter.

The baths require no sort of modification.

This arrangement can be applied to all kinds and sizes of cameras.

M. leard has communicated the following note upon Graduated Backgrounds:—

“Many contrivances for the attainment of this object have been described, none of which appear to me to be comparable, either in simplicity or in the results obtained, to that which I make use of. The following is a description of it:—I have made a little groove on each side of my pressure-frame, so as to admit of my introducing a piece of wood which completely masks the plate. An oval, of greater or lesser axis, according to the size of the object to be copied, is cut in the centre of this piece of wood. At the moment of exposing the frame to the sun's rays, or to diffused light, the whole secret consists in applying a piece of ground glass to the oval: the light reaching the picture only through this ground glass will give a gradation of tone of exquisite delicacy. In the absence of a piece of ground

glass a sheet of tracing paper will produce the same effect; the piece of wood can also be replaced by a piece of blackened cardboard with raised edges, fitting the frame exactly like a coverlid.”

M. Van Monekhoven has addressed to the secretary of the French Photographic Society the following communication upon the action of light upon certain compounds of silver:—

“In an article contributed by M. Roussin to the Society's *Bulletin*, which I have just received, I read that ‘Iodide of silver is not necessary in the albumen process in order to obtain images in the camera obscura. This salt only increases the rapidity a little.’

“I beg, sir, to refer you to No. 173 of the *British Journal* of the 1st September last, where you will find this fact stated in nearly the following words:—

“1st. In Young's experiment (consisting in the development of an image upon albumen after fixing) the image is not due to the iodide of silver, but rather to the albuminate of this metal.

“2nd. Every process in which, besides iodide of silver, there is present an organic body capable of combining with the nitrate of silver, will admit of development after fixing.

“3rd. In these processes the iodide of silver may be omitted in practice.

“The fact announced by M. Roussin is, therefore, a particular instance of the rule laid down.

“If, sir, any doubt lingers in your mind on this matter, I beg of you to peruse pages 322, 323 of the fourth edition of my *Traité de Photographie*, which I enclose.

“In my opinion, the theory of the formation of the image in the camera may be stated in these terms:—

“1st. In the processes where the iodide of silver is pure, or mixed with an excess of nitrate of silver, the action of light is purely physical.

“2nd. But in the processes where an argentic-organic combination exists in presence of iodide of silver, the action is double; first there is a physical action upon the iodide, then a chemical action upon the organic combination. Besides, the iodide of silver is not absolutely necessary in these processes in order to obtain images in the camera obscura. With regard to M. Roussin's second assertion, I have a few words to say—‘On the rapidity which iodide of silver communicates to the albumenized glass.’ I have, in fact, remarked the same thing, but the profoundest research has proved to me that this is due to the transparency of the albuminate of silver—a transparency so complete, that the light can impress several plates placed one over the other at the same time. But if the albuminate of silver be *opaque* (if the film be very thick), then the luminous rays are *stopped*; besides, I have not been able to discover in these conditions any difference between the sensitiveness of plates simply albumenized, and those albumenized and iodized.”

M. Davanne states, that on two several occasions he has proved that the abundant smoke of tobacco had an influence upon the development of negatives. In one of these instances a colleague attempted an instantaneous process in the presence of several smoking photographers: every negative was *fogged*. Next day he repeated the same process, after the room had been thoroughly aired and ventilated, and the images came out perfect. More recently, himself and a friend developed negatives taken by Taupenot's process, in the same room, with the same materials, and under identical conditions; with the one who smoked the developing solution soon became covered with reductions to such an extent that it had to be thrown away; while the other experiment, taken when the room was free from smoke, was perfectly successful. Numerous facts serve to prove the truth of these observations; and photographers who are in the habit of smoking in their operating rooms, may rest assured that this is the cause of numerous otherwise inexplicable failures.

INDIA-RUBBER PAPER. RESINIZED PAPER.

DEAR SIR,—At the beginning of last year, I tried printing on paper, prepared with india-rubber and gutta-percha, but was then unsuccessful, on account, as I since find, of my using too large a proportion of these bodies.

I have since tried some more experiments with the same substances, and some of them have turned out perfectly successful. I was much surprised to see that so many have been trying india-rubber, as I thought the idea of using it to render the paper waterproof before printing, had not been made public. As in the last number of the PHOTOGRAPHIC NEWS you say that you would be glad to receive practical details on the subject, I thought that your readers would like to know the proportions that I have found to answer best. Procure some pure benzole, and in four ounces of it, dissolve twelve grains more or less, of pure india-rubber. I say more or less, as different samples of india-rubber are very variable, as regards the extent to which they are soluble in benzole. Some of them swell up to an enormous size, and refuse to dissolve at all. After a suitable sample has been procured, and the correct quantity determined, it is best to keep to it. The india-rubber may be dissolved with advantage, in a little chloroform, before adding the benzole. When dissolved, allow the solution to stand till perfectly clear, then pour off the top portion with a flat dish. To prepare the paper, immerse in the way I directed for resinizing paper, draw it from the solution, and hang it up by two corners to dry. Great care is requisite to prevent streaks. Dust must be excluded, as far as possible, from the room, as any of it adhering to the paper whilst wet, would cause a kind of comet. When the paper is dry, it will present a beautifully even, and slightly glossy surface. The paper may now be floated on either of the following solutions:—

- No. 1.—Distilled water 1 ounce
Chloride of Ammonium ... 6 or 8 grains
- No. 2.—Chloride of Ammonium ... 6 or 8 grains
Iceland Moss..... 6 grains
Distilled water 1 ounce

The moss should be washed in cold water before pouring the boiling water upon it.

Or, No. 3.—The waterproof paper may be resinized.

The bath I used is 70 grains to the ounce, with $\frac{1}{4}$ drop of nitric acid.

By either of these three formulæ, charming prints may be produced.

The toning and fixing, is performed as usual.

A curious fact with regard to resinized paper, has recently come under my notice. I was much astonished to see a batch of prints remain, after fixing, as dark as when they were taken from the printing frames. I was at the time, at the printing establishment of one of our first photographers, and, as several prints printed there, did not lose at all, I was rather vexed that I could assign no reason for it, and to test whether it was to the chemicals used in toning and fixing that it was due, I brought a few prints away with me, and toned and fixed them at home, where they all lost considerably. I have since discovered the reason of this apparent anomaly, and now save a great deal of time, by not printing much deeper than the finished print is required to be. Upon removal from the printing frame I wash in two changes of distilled, and one of common water, and use a toning bath of acetate of soda and gold, in the proportion of 20 to 1, made at least a week beforehand, and never use either the toning or fixing bath more than once. From this, it will be seen, that if the print is washed at first in water, containing a chloride, and toned in a comparatively new bath, it will lose to a very serious amount.

Should you think this letter worth inserting, I should be glad if you would do so,—I am, dear sir, yours truly,

H. COOPER, Junr.

5, Aberdeen Park, Jan. 3rd, 1863.

Photographic Notes and Queries.

AMMONIA NITRATE BATH.

SIR,—Upon looking over the notices to correspondents, in the NEWS of the 2nd instant, one C. P. W. complains of blisters upon albumenized paper, floated upon the nitrate of ammonia bath. I beg to offer the remedy—namely, add a small quantity of alcohol; I use about four ounces in a 60 or 70 ounce bath, which at once causes the silver (as it were) to amalgamate as required, upon and with the hitherto repellent-surface.—I am, sir, yours obediently,

J. J. HOBBS.

WASHING PRINTS.

SIR,—Possibly the following idea has been already considered, but I have not seen it noticed. To every photographer, the washing of the prints is a dull, manual operation, without a gleam of science to enliven it. To supersede this troublesome process, I think that the air-pump might be applied, as follows: Place the prints in the receiver of the air-pump, and exhaust the air; this being done, admit water, which will of course immediately saturate the paper, then empty out the water, and again exhaust the air. Repeat this process, in proportion to the amount of the prints to be washed. The chemicals that dissolve in water will, I think, by this quick process, be carried completely away; whether the print will be damaged, can only be seen on trial. The experiment would require a very slight modification of an air-pump, and I would have tried it, but do not possess such an instrument, nor am I aware of the existence of one within sixteen miles of my residence. As I do not think that there is a photographer within the same distance, I have no one but you to consult, and trust you will pardon a "tyro" and "amateur" in so doing.—Yours truly, G. W. O.

PHOTOGRAPHY ON CANVAS.

SIR,—In the *British Journal*, Dec. 15, occurs the following:—

"On the same occasion M. Disderi announced that he had just been negotiating with an American artist, who had found out a means of producing positive pictures on the prepared canvas employed by painters. At M. Delessert's, and also at Disderi's, I have seen several specimens of this novelty, and must acknowledge that the result is most remarkable. The painter having only to terminate the sketch traced for him by photography, and being no longer inconvenienced by the nature of the substance he is painting upon, produces a work which has all the merit of photographic accuracy, and which at the same time has given him free scope for his talent."

I have no desire to detract from the merit or originality of the invention; but I shall feel obliged by your allowing me the privilege of stating, that as long ago as February, 1859, I had made experiments with a view of obtaining the same desideratum; and in March of the same year I had succeeded in producing perfect prints upon canvas as ordinarily prepared for the painter in oils, and had shown them to several photographers.

I hope to have several specimens of my process at the forthcoming Exhibition of the Photographic Society.—I am, sir, your most obedient servant,

Jno. T. LUCAS, Junr.

3, St. John's Wood Road, Regent's Park, Dec. 16th, 1862.

RESINIZED PAPER.

SIR,—My object in thus intruding myself to your notice, is to say a few words on the now controverted subject—photographic paper.

It is scarcely necessary here to remind your readers of the importance of the printing part of photography, as, thanks to your stirring articles on the subject, photographers have aroused themselves to take better care of this neglected part of the art.

We find most, if not all, photographers using albumenized paper in preference to any other, and yet albumen contains sulphur, the dread enemy of photographic prints; so we find in the very foundation of the proof sufficient cause for premature decay. Now, if any one paper at present in existence may be recommended, it is Mr. H. Cooper's resinized paper, described in one of your papers. This paper has many excellent points, and surely no better recommendation is needed than its well-known preservative qualities. I fear to presume too much on your time, or I would give you a formula for toning used by me, with the best results.—I am, sir, yours truly,

D. K. GRIFFITH.

Talk in the Studio.

CHEAP ALCOHOL.—A method of extracting alcohol from coal gas has been discovered at St. Quentin, France, by a young chemist named Cotelle. He announces that he can sell his alcohol at 25 francs the hectoliter, while the most inferior spirits produced from other articles is selling for 75 francs the hectoliter. One equivalent of alcohol contains 4 equivalents of olifant coal gas and 2 equivalents of water. There is nothing new about the obtaining of alcohol from gas; this has been done before but it cannot be manufactured so cheaply as from grain. Olifant gas can be made of alcohol as follows:—Take 1 ounce of strong alcohol and 4 ounces of concentrated sulphuric acid and place them in a glass retort capable of holding 10 ounces, and apply a gentle heat. When the liquor boils, olifant gas is given off. The sulphuric acid should be added to the alcohol in small quantities, and the retort should be shaken after each addition. The olifant gas thus obtained for experiment is usually passed through a weak solution of potash to wash it.

PORTABLE CAMERA.—We have recently had an opportunity of inspecting a very ingeniously contrived portable stereoscopic camera, invented by Mr. Hooper, and manufactured by Mr. Petschler of Manchester. The front is hinged at the bottom, and so arranged that it can fall back, with the lenses *in situ*, into the body of the camera. A case which holds three double backs, is attached with hinges to the back of the camera, but is so made that it can easily be removed. The whole, when packed up, forms a compact and convenient parcel.

NEGATIVE VARNISH.—We understand from Mr. Solomon, that a spurious imitation of the negative varnish of Soehnle Freres, has recently got into the market. As we have heard we have heard frequent complaints of the deterioration of this varnish recently, it is possible that this may account for the change. It should be an easy matter for photographers to assure themselves that they purchase a genuine article.

PHOTOGRAPHIC EXHIBITION.—Cards of invitation for the private view of the Exhibition of the Photographic Society have just been issued. The day is fixed for Saturday, the 10th, from twelve till dusk. On Monday it will open to the public.

THE ROBBERY OF LENSES AT THE CRYSTAL PALACE.—*George Restall*, late manager to Messrs. Negretti and Zambra, opticians, of No. 1, Hatton-garden, at their photographic establishment in the Crystal Palace, was finally examined, on Tuesday, at the Lambeth Police-court, on a charge of stealing photographic lenses belonging to his employers, of the value of £100. Mr. G. Lewis, jun., of Ely-place, appeared for the prosecution, and Mr. Sleigh for the defence. Sergeant Palmer, the officer engaged in the case, discovered that four of the missing lenses had been pawned at the shop of Mr. Blizzard, a pawnbroker, in the Borough, and that amongst them was one belonging to the prisoner himself. Richard Kinder, the shopman, swore positively the property had been pledged by the prisoner on the morning of Friday, the 31st of October last, and that he subsequently identified him at the Crystal Palace, when he had been taken into custody. Mr. Sleigh called three witnesses to prove an alibi; the first was the female servant of the prisoner, who swore that her master did not go out until after nine o'clock in the morning in question; and two relations deposed they left the house at a quarter past nine, preceded by omnibuses, and accompanied the prisoner to the Crystal Palace; while the pawnbroker's assistant swore positively that the accused pledged the property between the hours of eight and nine. Mr. Elliott, however, committed the prisoner for trial; but on the application of Mr. Sleigh admitted him to bail.

To Correspondents.

* Wanted, for full prices, or in exchange, the following numbers of the PHOTOGRAPHIC NEWS:—76, 80, 81, 91, 101, 197, 198, 200, 202, 203, 213, 214, 215, 216.

J. A. ACKLAND.—The amorphous iodide of ammonium, recommended by Mr. Ackland, is a preparation sold by Messrs. Horne and Thornthwaite, which decomposes much more readily than the usual crystalline samples, and, in Mr. Ackland's experience, gives greater sensitiveness and clearness. We shall be glad to hear further of your success with the iodide-chloride.

A.—The yellow stains are, probably, due to the prints sticking together in the fixing bath of hyposulphite of soda, and so preventing complete and

perfect fixation. A weak, or exhausted fixing bath, might aid in the result. Some trace of hyposulphite of silver is formed, and not dissolved at once by excess of hyposulphite of soda. The result is a yellow stain, which generally occurs in washing. The fact, that it most frequently occurs with vignettes, is confirmatory of this idea, as there is in such a larger surface of white paper containing unreduced chloride of silver, and more, therefore, to be dissolved.

AQUA PURA.—Vulcanized india-rubber would scarcely serve your purpose, as it contains sulphur. We don't see that you can use anything better than a piece of felt.

ROBERT REEKS.—The question entirely depends on the terms of the bargain. If you were employed to produce a photographic picture simply, whether it be a portrait, or a copy of some object, you have, according to the usual practice of the profession, completed your commission when you have delivered the print; the negative belonging to yourself, and, if given up, is generally the subject of a distinct and extra payment. If you were employed to take a negative of the painting in question, then, of course, it would become the property of the person who commissions the work. There is no law that we know of which affects the question, except usage, and that has generally determined hitherto, that, in the absence of an express bargain to the contrary, the negative remains the property of the photographer.

A CONSTANT SUBSCRIBER.—You may either print by development, fixing your negative in an aperture of the shutter of a darkened room, and enlarging on to the paper direct by means of an ordinary portrait lens, or what we should prefer, as simpler and better, take first a transparent positive, and from that a negative enlarged to the desired size. The details are too lengthy for explanation here; but you will find them given on more than one occasion in our last volume, and also in our YEAR BOOK for 1863, just published.

C. M.—We have repeatedly given the formulae and manipulations for toning with gold and acetate of soda. Use 3 grains of chloride of gold, and 90 grains of acetate of soda, in a pint of water. Mix at least twenty-four hours before use. We like the acetate better than the carbonate. See article on the subject in the PHOTOGRAPHIC NEWS ALMANAC, just issued.

S.—A report on your glass in our next.

H. J.—The dark deposit from decomposition in the toning bath is, doubtless, metallic gold. When it occurs, the only plan is to make a fresh bath. Alkalinity, organic matter, light, and a variety of causes, will sometimes bring it about, as well as free nitrate of silver. 2. We do not know of any cement which will unite strips of bladder together *strongly*, and yet remain flexible. Isinglass dissolved in vinegar might be tried, or india-rubber varnish.

HUGH ROBERTS.—If a stereoscopic negative, taken with a bi-lens camera, be copied as a transparency in a similar camera, no cutting or transposition is needed. Each half is, in the transparency, turned round on its own axis, which is practically the same as if the slide were cut in two. It is difficult to explain more definitely here without the use of a diagram, but, by trying the experiment, you will easily convince yourself. In reality the two images are cut, and each turned round in the camera on its own axis, the lens being able to turn round the image without cutting the glass. If you take the stereoscopic print, and after dividing the two halves, turn each round on its axis, so that the top is in the place where the bottom was; you will find you have simply produced the same change in their relative position as if you had transposed them, and this is what camera copying with a pair of lenses effects. Mr. Breese had one stand of Dallmeyer's stereoscopes with achromatic lenses, and another stand with similar stereoscopes by Cutts, Sutton, and Co., of Sheffield, both were first-rate instruments. We do not know any agent in London for those of Cutts, Sutton, and Co.

A. B. C.—Mr. England's use of the No. 1 B, in preference to the "new stereo" in the Exhibition building, was doubtless to enable him to get sufficient definition with a large aperture, having frequently to work in a very bad light. For stereoscopic work this is the chief advantage of the No. 1 B over the stereo lens, sufficient definition over the whole of the picture can be obtained with a much larger aperture, and thus, practically, greater rapidity is gained. Less subject is of course included in the same space with the No. 1 B, as the focus is longer. For interiors, and your purpose generally, we should be disposed to prefer the stereo. It is very rapid. As to the exact ratio of definition, light, &c., we cannot speak with certainty. The manufacturer can probably give you more definite information on that point.

AN AMATEUR.—In cold weather, and with some samples of paper, it will frequently happen that considerably more than ten minutes will be necessary to secure satisfactory tones, especially if the bath be old. Try much longer, or adding a little warm water with a trace of fresh chloride of gold. Vols. 2, 4, and 5 of the PHOTOGRAPHIC NEWS are in print, and may be had at the published price, namely, Vol. 2, containing the numbers of six months, 8s. 6d.; Vol. 4, containing the numbers of eight months, 10s. 6d.; Vol. 5, containing the numbers of twelve months, 15s. It is very doubtful whether we shall be able to make up any volumes at all of last year, as a great many of the numbers are quite out of print, and although we have offered full price for such numbers we cannot procure them.

S. L. G.—It is not necessary to be a member of the Photographic Society in order to exhibit. But we fear you are now too late, as the Exhibition opens on Monday next.

X.—The Ammonia-nitrate bath generally gives greater vigour than the ordinary silver bath. Mr. Hennah, of Brighton, has always used it for plain paper, and his tones have found many admirers. We think them a trifle too black. Tone is much a matter of taste, but a warm tone is generally more brilliant, and does more justice to a good negative than a cold one.

A. L. COKE.—There can be little doubt as to the custom of the profession. The negative belongs to the photographer unless a bargain to the contrary exists. You will find reports on *Mason v. Heath* on pages 115, 204, 234 of the PHOTOGRAPHIC NEWS, Vol. VI, or in Nos. 183, 191, 193. We do not know of any more copious reports. The paper to which you refer do not arrive. We shall be glad to learn the issue.

W. G.—Thank you for the cutting. We shall make use of it when the case terminates.

H. RANSOME.—If you wish to use that formula you should do so as it stands; but you may make an approximation by adding the lime to a solution of chloride of gold. See article in our YEAR BOOK, 2. Some persons prefer the lime and some acetate of soda. It is a question of taste.

THE PHOTOGRAPHIC NEWS.

Vol. VII. No. 228.—January 16, 1863.

THE PHOTOGRAPHIC EXHIBITION.

AN exhibition of the collected examples of any art is always a landmark of progress, looked for with eager anticipation, examined with careful scrutiny, and referred to in after-time as authoritative evidence of the exact state of advancement at a given period. The display of photographs at the International Exhibition of last year, we have always maintained, was not an adequate representation of the art. Apart from the antecedent misunderstanding and the unsatisfactory position, an exhibition representing the progress of eleven years, necessarily contained many things not new to photographers, and possessed much less technical interest than an annual exhibition. The Photographic Society very wisely determined not to exhibit in 1862, nor in any way divide the interest. This year, therefore, we have the examples of two years' progress to compare with the recollections of the last exhibition.

The ninth exhibition of the Society was opened for private view on Saturday, the 10th instant, and was attended by a large and deeply interested assemblage of visitors. The old Water-Colour Gallery in Pall Mall, where the most successful exhibitions, in former years, have been held, could not, unfortunately, be obtained this year, and the present exhibition is held in the rooms of the Society of British Artists, Suffolk Street, Pall Mall. So far as regards space, nothing could be more eligible than the present gallery, consisting of one large room and two smaller ones, and being in the immediate vicinity of the old place, it is convenient on that account. At present it possesses an important drawback, which is a serious detriment to the effect of the photographs. We refer to the want of light: the room is lighted by means of a skylight, on which appears to rest the accumulated dust and dirt of something like a century. This, added to the dark weather which has prevailed lately, renders it impossible to examine the pictures with any approximation to a satisfactory result. When the gas is lighted, the effect is wonderfully improved, but this, we fear, will not often be the case, as we learn with regret that it is not intended to open the exhibition in the evenings this season. The policy of such a course is, of course, decided by a comparison of receipts with costs; but we cannot but remember, that on former occasions the evenings presented the most animated effect, and have secured a full attendance. If it be at all compatible with commercial prudence, we would urge on the authorities the fact, that there are, in London, some thousands of photographers, whose only opportunity of profiting by the exhibition is in the evening. Operators, to whom such exhibitions are of immense educational importance, are closely engaged during the hours of daylight, making the most of the few working hours the season affords; and unless the exhibition be opened in the evening, they must lose all opportunity of seeing it, or, at most, obtain a hasty glance on some single occasion. If it be deemed imprudent, from financial considerations, to open the exhibition every night, we would suggest that it be opened one or two nights in the week, to which due publicity may be given. In any case, let us have light; let the dirty skylight be cleansed. Photographs pre-eminently require a good light for their satisfactory examination, and they lose considerably by the want of it.

The present exhibition is, so far as we can judge at present, a highly satisfactory one. Both in the number and excellence of the contributions it far surpasses those of

former years. The walls of the three rooms are well covered, and something like seventy frames remain unhung, rather from want of space than from want of merit in the pictures. The gentlemen entrusted with the hanging have, on the whole, executed their difficult and delicate task with great fairness and ability. Some modifications doubtless might be desired, but the necessity of making frames fit, as well as the importance of giving prominent positions to meritorious pictures having equally to be considered. Some of the contributions, which it might have been desirable to keep together perhaps, are somewhat scattered about; but this is better than hanging fine pictures in inaccessible positions.

In taking a general glance at the contributions, and reserving for future notices anything like a detailed criticism, we are struck with the amount of uniform excellence exhibited, and the absence of the sooty abominations which have startled us by their hardness in by-gone years. A higher general excellence prevails throughout, and leaves less room for contrast between the works of different men than existed in former years. There are much fewer white skies; there are fewer masses of soot and white-wash; there are few traces of sulphur toning. Some degree of photographic excellence, if not of artistic beauty, characterises almost everything we have noticed.

Prominently fixed on our memory, are the works of three contributors, as surpassing everything we have before seen in photographic exhibitions. These are the "Bringing Home the May," of H. P. Robinson, the "Photographic Studies," of Lady Hawarden, and the large instantaneous pictures of Lieut. Col. Stuart Wortley. The first, as we have before expressed our conviction, is such a picture as never before was produced by photography. It here occupies the place of honour, is the cynosure of all eyes, and excites alternate exclamations of wonder and delight from every visitor. Lady Hawarden's studies are small pictures, but of their class—and it is a charming class—they are perfect gems. As examples of *chiaroscuro*, they are wonderful; and as results, for the most part obtained with the management of light possible in a lady's drawing-room, they are a lesson to all photographers. The exquisite taste, fine feeling, and excellent photography, combine to produce an amount of pictorial effect very rare in photographs. Col. Stuart Wortley's instantaneous pictures of sea, and cloud, and foreground, and atmospheric effect, are sublimely grand. Le Gray has produced magnificent pictures of similar effects, but none like these. Warnod exhibited at the International Exhibition some very perfect large instantaneous views, but they lacked the sense of sublimity which these possess. Breese, Wilson, Blanchard, and Fry, have produced wondrously charming small atmospheric effect, but these are equal in beauty and rarity of effect, whilst they are on a scale rarely attempted in such work.

We have mentioned the three which have struck us most, because of their unusual style of merit; but there are many others of scarcely less excellence, but of a more familiar kind. Here are a splendid series of landscapes by Vernon Heath, from which we are delighted to see white skies entirely banished; a fine display of Francis Bedford's pictures, Eastern and English; Annan's noble landscapes; Henry White's exquisite bits of English scenery; Earl's grand interiors; Thurston Thompson's unrivalled reproductions, and a host of other landscape pictures the mere mention of the artists' names will guarantee their excellence. Here are landscapes by Mudd, Morgan, Dixon Piper, Spode,

Stephen Thompson, Major Gordon, W. W. Rouch, W. Mayland, Sir A. K. Macdonald, the Hon. W. Vernon, G. S. Penny, the Stereoscopic Company, the Amateur Association, and a host of others.

In portraiture, amidst much excellence, the level is more equally preserved. Pre-eminent in his own line, now as ever, are the vignette heads, of T. R. Williams; a large number of very fine pictures by Claudet; a few by Veron Heath; a frame by Mayland; some by McAndrew; and a few others well worthy of notice. The bulk of the portraiture is hung together in one room, a good portion of which is devoted to coloured work, much of which, so far as we can judge from a hasty examination, does not invite further attention, a great deal of it being sad stuff.

One of the most interesting features amongst the examples of portraiture is a series of prints on resinized paper from enlarged negatives, by Mr. A. Harman, Secretary of the South London Society. They are enlarged from card size to whole sheets of paper. The standing figures being about sixteen inches high. The original card is exhibited beside them, and we can unhesitatingly pronounce them to be the best pictures of their kind we have seen. The definition appears excellent, and delicacy and brilliancy are both secured. The enlarged prints appear in all respects fully equal to the small ones by their side, and the resinized paper appears to be admirably suited to the work. We shall examine these again by a good light with considerable interest, and commend them to the attention of all visitors.

There is not a large display of genre pictures. After those of Mr. Robinson, some by Bullock Brothers, also of Leamington, will attract attention, especially one entitled "Footsteps of Angels." This is a very bold attempt, and really striking in result. It is not, however, quite a success, as it fails in conveying its idea, also exhibits some solecisms, or incongruities, in lighting, to which we shall refer on another occasion.

Mr. Cooper has a glass case with some very charming specimens on silk, made into handscreens, watch pockets, &c., and also some fine specimens on resinized paper.

There is an unusually good display of stereoscopic transparencies, by Breese, Ferrier, Fry, Blanchard, and others, to which we shall refer in future. M. Claudet and Mr. England also exhibit stereoscopic pictures.

One room is devoted to foreign contributions, chiefly consisting of specimens from the International Exhibition. To these we shall advert on another occasion.

There are not many specimens of apparatus exhibited at present, two or three manufacturers only having sent contributions.

Owing to the tardiness with which packages arrived, the final steps for opening were taken in a somewhat hurried manner, so that a complete catalogue is not yet issued. We cannot, therefore, arrive at any satisfactory analysis of the processes represented; but so far as we can judge, the wet collodion process is represented in stronger force, compared to other processes, than at any former exhibition.

Scientific Gossip.

PREPARATION OF PURE HYDROBROMIC ACID—SPECIAL PRECAUTIONS TO BE TAKEN.

In our chemical articles we endeavour to place before our readers the most recent and practical information upon the various subjects likely to be of interest to them. Chemical science being, however, one of the most progressive branches of human knowledge, it constantly happens that the novelty of one day is superseded the next. In such cases as these we have adopted the plan of posting up our readers, in the particular subject in which improvement has been effected, by giving a short notice of it under the present heading, in preference to breaking in upon the plan and order of the series of our chemical articles. A case now occurs in which

information given some months back, and the best of its kind then attainable, now requires to be modified and enlarged to bring it down to the present state of science. We allude to the preparation of hydrobromic acid, a compound of considerable photographic value, both on account of its own properties, and also by reason of its forming the starting point to a long series of valuable salts. We will just glance at the different methods employed in the preparation of this acid. One excellent process consists in decomposing a solution of bromide of barium by diluted sulphuric acid. If sufficient care be bestowed upon it there is no great difficulty in getting a perfectly pure acid by this means, as by employing a trifling excess of sulphuric acid, and then distilling, a product is obtained, which is at the same time free from baryta and sulphur. The great objection to this process is, that it is necessary previously to prepare bromide of barium; otherwise it is a very good one. Another plan, is to distil bromide of potassium with dilute sulphuric acid; this involves the same objection as the one just mentioned; and is, moreover, not nearly so convenient, owing to the separation of sulphate of potash from the mixture, if the amount of sulphuric acid be small, and the decomposition of the hydro-bromic acid in the presence of a larger quantity of sulphuric into sulphurous acid and bromine. Balard's process is one of the least satisfactory of any, although it is one frequently used; he recommends passing hydro-sulphuric acid gas through bromine diffused in water. According to theory, the decomposition would consist simply in the hydrogen exchanging sulphur for bromine; but in reality another change goes on at the same time—the first portions of sulphur which separate, unite with some of the bromine, forming bromide of sulphur, and this decomposing in the presence of water, produces sulphurous acid. By far the best, as well as most economical plan, consists in preparing the acid by the reaction of bromine and phosphorus upon each other in the presence of water. These two elements have, however, so intense an affinity for each other that unless some special precautions are taken serious explosions will ensue. It is to these precautions and the modifications introduced into the process by one of our most skilful experimentalists, Mr. Maisch, that we wish to direct attention. A tubulated retort is taken, capable of holding at least double the amount of all the materials. Into the tubulus of this is fitted a funnel tube, and the neck of the retort is placed pointing upwards, and connected with an empty receiver, by means of a glass tube, which is cut off just below the cork; a second glass tube, commencing near the bottom, connects this receiver with another one of the same capacity—any ordinary bottles will answer—and dips into a little distilled water, both receivers being kept cool by ice, or some other means. The phosphorus is first introduced into the retort together with six or eight parts of water, if desired. The bromine must be added only in small portions at a time through the funnel tube, which is immediately afterwards covered with a glass plate. The apparatus is soon filled with white vapours of hydrobromic acid, mixed sometimes with free bromine; the vapours are partly condensed in the neck of the retort, and run back, they partly condense in the first receiver, whilst the last portions are absorbed by the water in the second bottle. This liquid will commence to rise in the tube when the reaction has subsided, and more bromine must now be added. This is continued from time to time until the whole has been used. The proportion of material is one part of phosphorus to twelve and a half parts of bromine. The first receiver generally contains some free bromine, besides some hydrobromic acid. The liquor in the last receiver will mostly be colourless if the condensed liquid from the first one has not been forced over through the connecting tube. If colourless, it is set aside and employed as the absorbing liquid in the next part of the process; if coloured, it is, together with the contents of the first receiver, added to the residue in the retort, and the

whole apparatus is then set aside, if possible, in the direct sunlight. The retort now contains phosphorus, bromine, phosphoric and hydrobromic acid. When it has become colourless after exposure to the light, and occasional agitation, the bromine has been converted into hydrobromic acid. The next step is the distillation of the hydrobromic acid, previous to which, however, every trace of uncombined phosphorus is to be removed. The neck of the retort is inclined, and the glass tube, after the first receiver has been disconnected, is made to dip into a small quantity of distilled water, or into the liquid employed during the first part of the process, if it was colourless, and had not to be subjected to another distillation; heat is applied, and the distillation continued to near dryness. The residue constitutes pure phosphoric acid. In this process, penta-bromide of phosphorus is first formed, which decomposes water when coming in contact with it, forming phosphoric and hydro-bromic acids. Inasmuch as concentrated phosphoric acid is apt to gradually destroy the retorts, it will be well to add after the undissolved phosphorus has been removed, six parts of bromide of potassium, and distil to dryness. As the solution in the retort becomes concentrated, by distilling off the liquid, a double decomposition is effected, resulting in phosphate of potash, and hydrobromic acid, the former of which is very soluble in water, and does not in the least impede the process. When the concussions are observed the fire is to be removed, and the tubulus of the retort opened; the salt becomes solid, and may, by dissolving in water and evaporating in a capsule, be obtained in a dry state. If the phosphorus contained no impurities, it will be pure phosphate of potash, and may be preserved as such for use. It is necessary to warn our readers on one point, which might otherwise produce serious accidents; that is, never to add the phosphorus to the bromine, inasmuch as the affinity of both elements is so great that the phosphorus burns in the vapour of the bromine, causing violent explosions, which may shatter the apparatus to atoms. By proceeding in the manner above described, there is no danger in the operation, the only annoyance being caused by the volatilization of a little bromine while pouring it into the retort.

The season for commencing photographic operations is beginning early, judging from the numerous specimens of glass which are forwarded to us for examination. No less than nine are at present on our table. Out of the whole number, however, there is only one at all fit for the purpose intended. Those marked 1, 2, 3, 4, and 5, are far too light, even 2 and 4 being not half dark enough. Specimens "Gillard 1 and 2" are too brown in colour, and transmit the actinic rays copiously. S 1 is a ruby glass, transmitting only the extreme red; it will certainly answer for photographic purposes, but not any better than orange glass, whilst it will render the room very dark for working in. S 2 has the fault of most of the other specimens, being too light, and of a brown colour instead of orange.

PHOTOGRAPHY: ITS RETROSPECTS AND PROSPECTS.

BY SAMUEL FRY.*

THE opening of a new year seems to offer a peculiarly suitable opportunity to take a slight retrospect of our doings as photographers, and to indulge in a few anticipatory views of the prospect which discloses itself at the commencement of a fresh season. Upon our late season we may look back with mingled feelings of regret and satisfaction—an alloy that, to a greater or less degree tinges all our mundane proceedings—of regret that a wet, cold, ungenial summer, should have to a certain extent marred our efforts, and acted as a hindrance to the prosecution of the desires of the enthusiastic follower of the new-born art; and of satisfaction that, notwithstanding official slights at the International

Exhibition, photography has triumphantly asserted its position, and that on any future occasion of the same nature we may feel sure its just claims will be recognized. Also, we have just cause for gratulation in the unquestionable fact, that the art-progress of photography has been fully commensurate with the expectations formed in advance; if, indeed, it have not in some respects surpassed them.

In instantaneous results—on which I have long insisted depends the future of photography—vast strides have been made; and so many accomplished labourers are now uniting their efforts, that it is only reasonable to expect great things in the ensuing year. Taking, then, all things into consideration, I am clearly of opinion that the prospects of the coming season are of the most hopeful character; and it remains for us individually, during the now short period of winter which must elapse before our active operations are recommenced, to determine fully in our own mind the line we intend to pursue.

I have, on previous occasions, urged the high importance of each taking for himself some particular line to delineate, and to devote all the energies to that, rather than by an incoherent following out of general principles to involve the mind in confusion, and, perhaps, to continue for a length of time pursuing an erratic course, and following a number of irrelevant subjects, without devoting a sufficient period to any single one to obtain proficiency therein. These remarks will apply with especial force to gentlemen whose time for these matters is very limited, and for whom it is of paramount importance to have clear, distinct intentions.

So many subjects, all of surpassing interest—some of them almost sublime in the beauty of their results—open upon the mind that any one, especially a tyro, may well be excused for hurrying for a time, butterfly like, from flower to flower. He tries in turn portraiture, landscape, stereoscopy, instantaneous works, albumen, collodion, dry plates, enlarging, microscopic reduction; there seems no end to the field, no limit to the value, commercial as well as artistic, of the subject.

We have now, thanks to eminent opticians and clever mechanists, exquisite lenses and admirable apparatus; our chemicals are more certain than ever; iron development and separate toning and fixing, have changed the whole aspect of affairs within a year or two, and there is now more scope than ever for the artistic photographer. Clean working can no longer carry off the palm, so large is the number of those who are able to fulfil all that can be desired in this way. No! photography must take higher ground, and assist in an uncontrovertible manner its intimate alliance with the fine arts. The painter, with a proud conception pre-arranged in his mind, looks to nature for his inspirations, and secures in his sketch-book studies called here and there; sunny skies, browsing herds, trees, rocks, and all that nature or art, judiciously selected can furnish to enrich his canvas and enhance his reputation. It is competent—nay, it is incumbent—on the photographer to do this also, if he desire to be of the same class, and to enforce the dogma that our art, when perfected by the united discoveries of science, and labours of the artist, should be entitled to rank as a fine art.

ON THE ACTION OF LIGHT ON BROMIDE OF SILVER.

BY M. AUG. TESTELIN.

IN almost all photographic processes in which iodide of silver forms the principal basis of the sensitive material, a certain quantity of bromide is added, corresponding to the soluble metallic iodides which must subsequently form the salt of silver by double decomposition with the nitrate of the sensitizing bath.

To the bromide of silver—which thus necessarily results in the preparation of papers or plates coated with collodion or albumen—belongs the peculiar property of being im-

* Read before the South London Photographic Society.

pressed under the action of the yellow and green luminous rays, differently and more easily than the iodide is, under similar circumstances.

In order to overcome the difficulties experienced in the representation of subjects in which the tints are very varied, and opposite in their chemical action, it is customary to introduce into the collodion a relative quantity of soluble bromides corresponding to the iodides which form the base of the generating salts, and by this addition we render coloured objects more completely than could be hoped for as perfect by any other means.

This fact is very important in photography, and has induced us to examine into the fundamental principle; whereupon we perceived that an error, apparently confirmed by experiment, had led to the conclusion that the action of coloured light upon bromide of silver, differs from that which this agent exercises upon the iodide of the same metal obtained and preserved under the same conditions. It is generally admitted that the green and yellow rays of the solar spectrum act relatively with greater activity upon bromide of silver than the other coloured rays; but if this fact be substantial and demonstrated in practice, the principle attributed to it is altogether illusory, as we shall attempt to show.

Suppose, for example, that we project the solar spectrum upon a white screen, in order that, by thus arranging a series of very pure and vivid colours, the experiment shall be clear and definite. In the place of this screen, substitute a glass plate covered with collodion prepared with iodide only (without bromides). After ten or fifteen seconds, withdraw the plate, and develop it with a weak solution of sulphate of iron, prepared in the usual manner, and there will appear a black confused trace along the entire length of the spectrum, extending from the red to the violet, and even beyond it. Upon examining the negative, we further discover that the portion impressed by the violet rays is grayer and more transparent than the rest, which indicates too long an exposure.

Experimenting afterwards with fresh plates, we reduce the time of exposure to the coloured spectrum until the most active portion (the blue and violet), has produced its maximum effect, without, however, exceeding it. Let us suppose that this space of time is a second, for example; after examining this last negative, we remark that the image obtained does not extend so far as before, and that the luminous action diminishes from the blue towards the green.

From these experiments we conclude:—

1. That the iodide is susceptible of being changed by all the coloured rays of the solar spectrum.

2. That this action is stronger with the violet, blue, and green rays, and much less active with the yellow, red, and orange rays.

3. That the action which light can exercise upon iodide of silver may be easily excessive, when there is chemical decomposition, and the effect of the developing agents no longer produces a picture, or at least, they act more feebly in causing the image to appear.

This last property, therefore, opposes itself to prolonging the exposure to light in order to obtain an impression from the green, yellow, orange, and red rays. Now, if we operate on a sensitive substance, which does not possess, like iodide of silver, the property of being "over-done" when developed, it is, of course, sufficient to prolong the exposure within determined limits, for this or that coloured ray to have time to produce an action which may be regulated in such a manner as to be relative to its apparent intensity, compared with the hues of the whole object.

It is precisely this property which is possessed by bromide and chloride of silver; these salts will even take a deeper tone under the action of light, without, in consequence, losing the property of being darkened by developing agents.

This characteristic of bromide of silver, then, very clearly

explains why this salt appears more sensitive to the green rays than iodide of silver, as it is equally susceptible to all the other coloured rays. Added to iodide of silver in the sensitive film, it in no respect modifies its properties, nor communicates new ones; on the contrary, where the solar rays have only a feeble action, it performs no part at all; but it is only where the light is so strong as to decompose the iodide of silver wholly, after a sufficient space of time, so to speak, to effect the chemical change, that the bromide of silver is found impressed in the limits necessary to render these parts of the picture in harmony with the rest.—*Bulletin Belge de la Photographie.*

A "SPIRIT" PHOTOGRAPH.

BY DR. T.L. PHIPSON, F.C.S., ETC.

SOME years ago, a friend of mine in Bruxelles received a box of glass plates for photographic purposes. They were highly polished, quite new, and each separate plate was enveloped in two or three folds of the journal *L'Indépendance Belge*. One of these plates was taken out and prepared to receive an image. The sister of the gentleman before alluded to, sat for the picture. In course of time, the plate was developed and finished, when, to our astonishment, the whole of the image obtained was covered with printed characters, which it was not difficult to identify with those of the paper which had enveloped the plate.

The "spirit" was, in fact, *the ghost of a political article in the Indépendance Belge.*

CARBON-PRINTING.

BY A. LANDER.

PERFECT confidence in the stability of photographs printed with the salts of silver cannot be said to be established; and no one would venture to guarantee the existence of a picture ten years after it has left the hypo bath.

This instability is most probably due, mainly, to defective washing of the proofs; but even supposing the washing to have been most carefully and effectually performed—a fact the purchaser can never ascertain for himself—still the permanence of a picture cannot be guaranteed; for the atmosphere abounds in agents capable of attacking the thin metallic coating which forms the picture; and skilful chemists, such as M. Regnault (the President of the Photographic Society of Paris), even think that this metallic film may evaporate or diffuse itself in the substance of the paper.

For photographic pictures to possess a degree of permanence equal to that of engravings and lithographs, it is absolutely necessary for them to be formed of insoluble substances, as little volatile as possible, and unattackable by sulphur, ammonia, and nitrous fumes. If to these conditions we add that of the picture being of a fine black colour, similar to that of printing ink, our choice becomes limited almost entirely to carbon in powder. Seven or eight years have elapsed since the first attempts were made to produce carbon photographs; the scientific possibility of success depended upon the existence of substances which become hygrometric, or cease to be so, under the action of light, so that the parts impressed by it, or those which are not, become susceptible of fixing pulverulent matters. But until the commencement of the present year, the results attained in no respect the perfection of proofs furnished by the old processes, and possessed no value other than as curiosities.

In the month of March last, M. Charavet, photographer, of Paris, exhibited a series of carbon prints, both portraits and landscapes, which were greatly admired. These photographs, in finish and delicacy, could be distinguished from proofs taken with the salts of silver only by their permanence in the presence of nitric acid, and by the beauty of

the black tones. It was now evident that the problem of permanent photography was resolved, both in a scientific and in an artistic point of view, and that it was only necessary to discover the most practicable and economical manipulations. To enquiries as to the method he adopted to produce these carbon pictures, M. Charavet gave only evasive answers. Since then, however, he has communicated to us the theory of his process, and entrusted to us some memoranda which will enable us to afford some useful information to our readers.

The chemical principle of M. Charavet's process is, that a mixture of gelatine and an alkaline chromate, prepared and dried in the dark, becomes deliquescent and soluble in water when submitted to the action of light. This property of gelatine has been known for a long time. We cannot say who discovered it; but since the year 1843,* M. Mungo Ponton has made it the basis of positive printing, in which coloured proofs were obtained by the chromates of different metals.

M. Poitevin, well known also by his curious lithographic process, conceived in 1855 the happy idea of incorporating carbon in powder with a chromated gelatine. By spreading this mixture upon a sheet of paper or other surface, and causing the light to act upon it through a negative, and afterwards washing the impressed gelatine, the water removes all the parts which have received the action of light, and the carbon remains only in the blacks. Unfortunately, this method does not furnish half tones, because in them the surface only of the gelatine has become insoluble, and they are entirely removed by the washing, along with the pure whites.

In 1860, M. Fargier, of Lyons, discovered a remedy for this inconvenience. It consists in the application of the following process, suggested in 1857 by M. Moitessier, for transferring a picture from glass to paper. In his patent Mr. Fargier describes the manipulation nearly in the following terms:—"Upon a plane surface, such as a glass plate, spread a film of sensitized gelatine holding a carbonaceous powder in suspension, and dry it in a darkened room; then expose it to the light. Then coat the plate with collodion, and immerse it in warm water; remove the collodion from the plate, to which it adheres only at the edges, and after several washings, place it upon the piece of paper on which it is to remain."

We do not consider it necessary to enter into details to explain how, during the washing, the water acting from the thick portion to the thinner portions of the film of gelatine, and not from the thin to the thick, can preserve the half tones. We say, *can preserve*, for in fact they are not always preserved, or are sometimes too much so. The pictures shown to us by M. Fargier were extremely defective, and could not be offered for sale, for they made every person look like a negro.

M. Charavet operates by M. Fargier's process, but by improving upon it he has obtained the remarkable results which have excited our attention.

Other methods of carbon photographs appear to yield very good results, but their principle is different; it consists in the fact that the salts of protoxide of iron, with organic acids prepared in the moist way, are naturally hygrometric, and cease to be so when they have been exposed to light. A collodion glass plate, impregnated with these salts, becomes, therefore, capable, in those parts which have not received the action of light, of causing powders, spread with a brush, to adhere to those parts. M.M. Garnier and Salmon took out a patent in 1859 for this process, the principle of which was announced by Herschell in 1842. More recently, M. Poitevin has discovered the counterpart of this principle; which is, that the per-salts of iron, mixed with reducing substances, are not naturally hygrometric, but become so in the light.

To complete what relates to permanent photographs, we

must not omit to mention the labours of M. Lafon de Carmasac. Since 1855, some time previous to M. Poitevin, he obtained photographs which were almost indestructable, but he overshot the mark. Instead of seeking to make permanent photographs upon paper, he regarded the paper itself, which can endure only a few centuries, as a substance altogether too ephemeral, and constrained himself to employ only ceramic media, such as porcelain, glass, &c. The chemical principle to which he had recourse is, that bitumen of Judea, dissolved in oil of lavender, acquires (or loses?) the property of adhering to coloured powders after it has received the luminous impression. Disregarding the difference in medium, it is therefore M. Lafon de Carmasac who must be considered as the inventor of carbon-printing. But, in truth, there is no need to speak of the *inventor* of a thing which exists only through the combined efforts of several persons; and we can only regard the inventor of carbon-printing in the same light, for instance, as the inventor of the steam-engine.—*Presse Scientifique*.

STUDY OF THE WET COLLODION PROCESS.

BY M. E. REYNAUD.*

4. *The Negative riddled with pin-holes, produced during Development, and also after Intensifying and Fixing.*

The principal cause of the first of these accidents is the presence of an excess of iodide of silver on the collodion film, after sensitizing.

This excess is produced when the collodion employed contains too great a proportion of alkaline iodide, relative to the thickness of the film it furnishes; that is to say, relative to the proportion of pyroxiline dissolved. However, a collodion in these conditions cannot produce the bad results indicated above, if it be sensitized in a strong new bath. Then, in fact, the nitrate will dissolve the excess of iodide of silver, and the collodion film will be in the best possible condition. But if the sensitizing bath be already saturated with iodide, the following condition arises:—the film being too thin to retain all the iodide that is formed, part of this salt is separated under the form of extremely fine and opaque grains, which, not being dissolved by the nitrate of the bath, adhere to the surface. During the exposure to light these grains are impressed by it, and, acting as screens, they prevent the lower film from experiencing the luminous action. At the time of development, these pulverulent grains are driven off by the stream of the developing solution poured upon the plate; and thus exposing the non-impressed parts, which are transparent, they form a quantity of little holes, which being reproduced as black spots upon the positive, completely spoil it.

Moreover, these impressed and floating molecules attach themselves almost always to the film, upon which they are found spread uniformly, in consequence of the agitation communicated to the plate during development. They therefore necessarily cause a uniform veil, which destroys all transparency in the darks and all delicacy in the details.

We perceive that it is easy to remedy these accidents, as it is sufficient to that end to take care not to dissolve more than a reasonable proportion of iodides in the collodion (as indicated previously); and by replenishing, at least in part, a bath already saturated by the plates which have been sensitized in it.

We sometimes also obtain negatives riddled with small holes by another cause, which it is as well to know how to avoid. I refer to the acetate of silver, resulting from the addition, to the sensitizing bath, of a certain quantity of acetic acid. This acetate of silver, but little soluble in the nitrate, is still less so when this latter is concentrated; consequently, it will be perceived that every collodion plate, sensitized in a bath of this kind, precipitates a certain quantity of this acetate under the form of very small

* Mr. Mungo Ponton first announced his discovery in 1833.—Ed. P. N.

* Concluded from p. 427.

ystals. These crystals fix themselves in the film, and being removed or dissolved in the subsequent operations, they leave the place they occupied, vacant and thus riddle the picture with small holes. Upon examining a negative thus spoiled, by a microscope or simple magnifying glass, it is very easy to recognize the nature, and consequently the cause, of this accident.

If it be due to the precipitation of iodide of silver, the holes are irregular, and do not exhibit crystalline forms; if, on the contrary, these holes result from the crystallization of the acetate of silver, they take a crystalline form, and this character permits of our recognizing them easily.

Frequently, after developing a negative, we can perceive no signs of these points; but after strengthening and fixing, we are disagreeably surprised to see them appear, and spoil a negative supposed to be perfect. This disaster may always be avoided by employing an intensifying solution of nitrate of silver both new and weak, (about 3 per cent, at most).

For when, to turn old baths to account, we intensify with silver solutions saturated with iodide, we precipitate upon the negative—in consequence of the addition of the aqueous solution of sulphate of iron or of pyrogallic acid—a certain quantity of this iodide of silver which adheres to it, and becomes incorporated among the molecules of reduced silver; and which, being afterwards dissolved by the solution of cyanide of potassium or of hyposulphite of soda, also produces, as in the preceding cases, a negative riddled with holes.

This effect is also produced less regularly when we employ an intensifying solution of nitrate of silver freshly made but too concentrated (especially if the developing solution be new). The reduction is then made in too great abundance, and the particles of silver assume large dimensions, adhere very slightly, and are removed by washing the plate, leaving great holes in the place they occupied.

By this we perceive that, in order to obtain fine pictures, we must operate with weak solutions, and with collodions slightly iodized; in a word, we must moderate the reactions, and avoid producing them suddenly, for this promptitude is always at the expense of the fineness of the grain and the perfection of details.

5.—*Complete Fogging of the Negative.*

Many different causes may produce this unwelcome result, one most frequently encountered by inexperienced operators. I shall examine each one in succession:—

- 1st. Fogging produced by certain iodides, and by too great neutrality of the sensitizing solution.
- 2nd. That which results from a bad state of the surface of the glass plate, added to a too porous state of the collodion film.
- 3rd. That which is due to the action of light, either before, during, or after exposure in the camera obscura.

A collodion containing only iodide of cadmium, without free iodine, sensitized in a neutral bath, or in one very slightly acid, will always give fogged negatives, without this result being attributable to the action of light; for the fogging will, under these conditions, still make its appearance, although the plate be kept constantly in complete darkness.

To neutralize this property of iodide of cadmium, it is sufficient to add a little free iodine to the collodion, and a little nitric acid to the sensitizing bath. If this does not suffice, the addition of a little iodide of potassium or of iodide of ammonium to the collodion will infallibly put a stop to these abnormal reductions.

The second kind of fogging enumerated above is produced when the collodion contains pyroxyline of bad quality, or too great a proportion of alcohol. The collodion film is then too penetrable to the various liquids; and then, upon developing, a certain quantity of the iron and silver solution infiltrates between the collodion and the glass plate, and (if the plate be not perfectly clean) there results a reduction under the picture, which often entirely spoils the negative, or at

least destroys the vigour of the shadows and the beauty of the details.

A glass plate, perfectly clean and dry at the moment the collodion is poured upon it, is necessary in order to avoid this accident; and as to the proportion of alcohol contained in the collodion, we have never anything to fear in employing it in the proportion of one part to two parts of ether, as before stated.

The collodion and the baths being thus prepared and harmonized, we may always avoid the foggings described above; but if the negatives still be grey, and not transparent in the darks, or if, when viewed as *positives*, they exhibit a uniform tarnished aspect, we may then be certain that the fogging is the result of the external action of light, and we must make sure that none penetrates into the camera obscura. Lastly, we must guard against the admission of white light into the operating-room, however small in quantity, though we have nothing to fear from yellow or orange rays, coloured so by passing through glass of the proper colour.

Under these conditions, I can assure the photographer that, with a little practice and dexterity, he may certainly attain a good result in most cases; at any rate he has the means of tracing the causes of failure, and of remedying them.

The wet collodion process is unquestionably the most perfect photographic process known at present, and its applications are the most general and numerous. I believe, therefore, that, notwithstanding the numerous essays and formulæ on the subject, it was probably not unimportant to collect and classify the most frequent causes of failure. I shall have accomplished my object if some of these indications prove useful to the numerous adepts of an art, the importance of which increases daily.—*Le Moniteur de la Photographie.*

ALCOHOL IN THE SENSITISING BATH FOR ALBUMENISED PAPER—THE PHILOSOPHY OF ITS ACTION.

DEAR SIR,—No one who has even cursorily investigated the subject, can have any doubt that the belief in the possibility of coagulating dried albumen, has very much retarded the advancement of our knowledge as to what is essential for the production of the utmost brilliancy in photographic prints upon albumenised paper. That photographers—whether chemists or not—have given universal credence to this fallacy, cannot be denied with any truth, when the fact is borne in mind that not any individual amongst them has ever attempted to expose it; whilst very many of them, in England, France, and America, &c., who are men of science, are, at the present time, persistently assuming it to be a fact, and attributing to this fancied coagulation the effects which are produced from other causes.

As water is the solvent employed for the salts used in the sensitising, toning, and fixing baths, and the prints have not only to be submitted to its action in these three processes, but have also, in their final washing, to be immersed in it for several hours; and as dried albumen is also soluble in it, an absolute necessity arises that insolubility should be produced by sensitising; this the nitrate of silver accomplishes, by forming with it an insoluble compound, and the sooner it can be effected, the less will the brilliancy of the albumenised surface of the paper be impaired.

Did we use any solvent for the nitrate of silver that was not also a solvent of dried albumen, a weak sensitising bath would be sufficient, not only to form the albuminate and chloride of silver, but likewise to afford the requisite free nitrate, by a longer or shorter floating, according to the strength of the bath. Absolute alcohol not being a solvent of dried albumen, it follows, as a natural consequence, that a considerable portion of it in the sensitising bath, must diminish the solvent power of the water; therefore, the greater the strength of the alcohol, and the larger the

quantity added to the bath—not only the less silver requisite in it, but also the less time required for floating the paper: as the silver salt, from not having so much antagonistic force to contend against in the solvent power of the water, is enabled to produce insolubility by its combination with the dried albumen *sooner* than it could under more adverse conditions.

Thus, upon philosophical grounds I think it may be inferred, that the addition of alcohol to the sensitising bath for albumenised paper, will be an advantage. The Abbé Laborde's conclusions are, therefore, correct, *but not the cause assigned for them.*—Vide "Foreign Science," p. 609, of your Journal for Dec. 19th, 1862.

Unfortunately, the belief in *one* fallacy causes the promulgation of *others*; thus we find the Abbé, who is a man of science, stating, that the dried albumen "is coagulated both by the nitrate of silver *and* by the alcohol." With alcohol in the sensitising bath, we have two ingredients, *both* of which are assumed to have the power of coagulating the dried albumen; but even *did* they possess the power falsely attributed to them, *they could not act in conjunction, for the weaker power must give way to the stronger*; the alcohol, therefore, only serves the purpose of *mitigating* the solvent power of the water, *and has no action whatever itself upon the albumenised surface of the paper.*

Yours truly, GEORGE PRICE.

Mornington Road, New Cross Road, Deptford.

THE CHLORIDE OF CALCIUM BOX.*

BY CHAS. WALDACK.

SENSITIZED paper, although kept in perfect darkness, sometimes turns brown in a few hours. This alteration, which is caused by the action of nitrate of silver on the sizing of the paper, is principally observed in damp weather. Albumen paper is more liable to it than plain salted paper, and such as is sensitized with ammonio-nitrate more so than one floated on a simple solution of nitrate of silver. When kept in a perfectly dry atmosphere, however, even albumen paper floated on ammonio-nitrate of silver will keep for several days. To attain this object, use is made of the properties of *chloride of calcium*, a salt which absorbs moisture with great avidity, and which, for this reason, is used as a desiccating agent in chemical operations. The apparatus consists of a square or round zinc box with a very light-fitting cover. In the bottom of the box is put a sheet-iron pan, filled with dried chloride of calcium. Above it, and resting on a border, is a wire frame on which is laid the sensitized paper. A professional photographer should possess two of these boxes—one in which to keep his sensitized paper, and another in which to keep the prints until the time comes for toning. It is readily seen that the box should be left open as little as possible, to keep out the moisture. Perhaps some improvement might be introduced by which it would not be necessary to take off the cover every time a piece of paper or a print was put in. For instance, the cover might be pierced with a hole, on the top, through which the prints might be slipped into the box, and this hole might be shut by laying a heavy ground glass over it; or, better yet, with an easily fitting cover.

For more security against the entrance of moist air, an india-rubber band might be stretched around the joint of the large cover. After being used some time, the chloride of calcium becomes wet. When this happens, take out the sheet-iron pan containing it, and leave it on the top or in the oven of a stove until the salt is again dry. This operation can be performed over and over again without losing its quality.

It is to be hoped that some one of our enterprising manufacturers will take the matter in hand and furnish this useful apparatus to American photographers.

* From *Humphrey's Journal*.

The credit of this simple, yet useful, invention is due to Messrs. Barresuil & Davanne, two chemists to whom photographers are greatly indebted, and who have written the best work on photography in the French language.

PHOTOGRAPHIC PIRACY OF ENGRAVINGS.

GAMBART v. BALL.

THIS was an action tried before Mr. Justice Willes at the last sittings at Guildhall, when a verdict was found for the plaintiff—damages, £10.

Mr. COLERIDGE, Q.C., on Tuesday last, moved on leave reserved to enter a nonsuit, on the grounds that there was no evidence to go to the jury, and that there was no infringement of any Act of Parliament. The question arose on the right to publish photographic copies of certain prints, and whether so doing was an infringement of the Copyright Acts. The plaintiff was the proprietor of the prints, "The Horse Fair," engraved from Rosa Bonheur's picture, and of "The Light of the World," engraved from Hunt's picture. The defendant, among other photographic scraps, had sold a copy of the print, "The Horse Fair," and also a photographic copy of the other print, and the jury found that they were copies taken from the engravings themselves. The learned counsel contended that these photographic copies of the prints in question would be no infringement of the plaintiff's copyright, unless within the words of the Copyright Acts. The first of these Acts was the 8th George II., cap. 13, which gave any person who invented a design, or engraved or etched it, the sole right and liberty of printing it for 14 years. This was to protect the artist or inventor of the picture. The next statute was the 7th George III., cap. 38, which extended the provision of the former statute by prohibiting any person to engrave, print, or publish, or import for sale, any copy of a print in which any person had a copyright.

Mr. Justice WILLES.—That is a protection of engraving against engraving, not of engraving against drawing; *a fortiori*, not against a new mode of drawing.

Mr. COLERIDGE.—That was so. The next statute was the 17th George III., cap. 57, which prohibited "that any person should engrave, etch, or work, or in any other manner copy, in whole or in part, any print in which there was a copyright." This statute, the learned counsel contended, did not extend the protection against any other kind of piracy than that which before existed. The next statute was the 6th and 7th William IV., cap. 59, which extended the provisions of these Acts to Ireland. The last statute was the 15th and 16th Victoria, cap. 12, which, by section 14, extended the protection of the Copyright Acts relating to prints against lithographs or any other mechanical process by which prints or impressions of drawings or designs are capable of being imitated. The learned counsel submitted that photographs were not within the meaning or protection of any of these Acts, nor was a word said about photographs in the treaties regarding international copyrights.—Rule *nisi* granted.—*Times*.

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this society was held in the City of London College, on the evening of Thursday, January 8th, Mr. Sebastian Davis in the chair.

The minutes of the previous meeting were read and confirmed.

Mr. A. HARMAN, the Secretary, exhibited a couple of prints from enlarged negatives; one an architectural subject, on albumenized paper; the other, a portrait, enlarged to a full sheet of paper, from a card picture, printed on resinized paper. Both were good, the latter especially so, being well defined, delicate, soft, and artistic.

Mr. WALL, commenting on this picture, said that it proved, in a very satisfactory manner, that resinized paper could render transparency in the shadows. Some who had doubted this had mistaken the depth given by the albumen for depth and transparency in the picture.

Mr. COOPER observed, that the specimen on the table was not rolled, and that a greater amount of detail in the shadows would be apparent after it was rolled.

Mr. WALL said much misapprehension seemed to prevail amongst photographers as to the true meaning of the term "transparency," as applied to the shadows of a picture. Transparency was simply the result of detail, which carried the eye into the deepest shades. It might exist without a glossy surface at all, and might be absent, no matter how high the glaze; it was a great error to suppose that the glossy surface of albumen necessarily gave transparency. Rolling, as well as glazing, would sometimes bring out detail in the shadows not before apparent, and thus Mr. Cooper was correct in referring to rolling as a means of giving additional transparency.

Mr. HARMAN thought resinized paper would not come into use for small pictures; but for whole plates and upwards he thought the results were so much more artistic, that it would come largely into use.

After some further conversation,

Mr. COOPER said, he had recently spent a few days with Mr. T. R. Williams, at his establishment at Finchley, where the printing was done. He had there been struck with the fact that, in the method adopted, very little printing was necessary. By following the same plan, he now found that, both on resinized paper and silk, he could get good results with much less printing than he had formerly recommended. It was simply necessary to wash the prints in distilled water, instead of common water, then tone with a bath of acetate of soda and gold, which had been made a week, using it only once.

Mr. LEAKE said it was well understood that the acetate bath was better for being made three or four days, or a week, before use.

Mr. COOPER said, that in using the solution only once there was not necessarily much loss, as a very small quantity of solution might be used.

Mr. HARMAN generally used the solution seven or eight times, and liked it better after it had been used once or twice than at first, as it seemed to prevent any tendency to meanness.

Mr. G. WHARTON SIMPSON said he thought the observation made by Mr. Cooper, as to the practice in the printing establishment of Mr. T. R. Williams, was very important. He (Mr. Simpson) had often been somewhat puzzled when Mr. Williams informed him that in his establishment they over-printed very little; the depth of the print, when it left the printing frame, being very little more than what was required in the finished prints. Mr. Cooper, when there, had been printing on resinized paper and silk, and found, when using Mr. Williams's solutions, his prints, printed the usual depth, were much too dark. He thought, perhaps, that he was deceived by the quality of the light, and printed a little lighter, but the results were still too dark; and it was not until he printed to just about the depth required on the finished print, that he obtained what he wanted. It was clear that the prints lost scarcely anything in the processes of toning and fixing. After careful observation, he found that the chief difference between his own operations and those in Mr. Williams's establishment consisted in the fact that whereas at home he used common water, here they used filtered rain water. On returning home he tried distilled water, and found that it made all the difference in the depth of printing required. It would seem that the effect of water containing chlorides was to act upon the print, perhaps converting some of the minutest particles of silver, forming the image, such as those in the half tones, again into a chloride of silver, which caused the prints to be considerably reduced by the action of the hypo bath, and by this circumstance rendered necessary much over-printing whenever common water, or water containing chlorides, was used for washing before toning.

The CHAIRMAN said members would remember that some time ago he recommended the use of distilled water, and floating the print instead of immersing it, so that the free nitrate would dissolve, and by its superior specific gravity fall to the bottom of the water.

Mr. HARMAN thought such a plan would require too much time, where printing was conducted on a large commercial scale.

After some further conversation, in which the Chairman commended the subject of resinized paper as one which would well repay further experiment,

The CHAIRMAN said Mr. Simpson had handed to him a copy of the PHOTOGRAPHIC NEWS ALMANAC for 1863, for presentation to the Society. All who had seen last year's almanac, would, he felt sure, look for this one with much pleasure, as forming a most valuable and complete epitome of the science

and art of photography up to the present moment. He then called attention to some prints which had been under water for some time, in the *Colombo*. The action of the salt water had been to change the colour to a light, dirty, yellowish brown.

After some further conversation,

Mr. SAMUEL FRY read a paper on "Photography: its Retrospects and Prospects." (See p. 27). At the close of his paper, he explained that his aim had been rather, by a few brief remarks, to promote discussion, than to bring any especial views of his own before them. He thought greater things would be effected in photography if each artist were to select a given line, and stick to it, in preference to perpetually experimenting in different directions. He urged upon all photographers the effort to attain a higher artistic standard.

Mr. WALL referred to the practice of capable professional photographers, who worked down to the standard of imperfect public taste, instead of endeavouring to elevate that taste to a higher standard. Painting had once been in the same position, but had at length risen beyond it, and he hoped photography would soon do the same. He referred to a recently published work, entitled "A Painter's Tour in the Highlands," said to be written by a distinguished art critic. This book devoted a chapter to the consideration of photography as a fine art. Notwithstanding an evident disposition to be just in his appreciation of photography, it was impossible to avoid a smile at the profound ignorance of the subject manifested, as evinced in his treating as inherent faults of the art those shortcomings which were entirely due to bad lenses or bad manipulation, and overlooking the important fact that all art is subject to similar defects when in the hands of incompetent persons. The legitimate conclusion of such a line of argument would be to condemn all art for the shortcomings of artists. His object, in drawing attention to the subject, was to impress upon members that one great duty photographers owed to their art was to endeavour to make it understood in principle, as well as appreciated in result.

After some further desultory conversation,

The CHAIRMAN remarked, that whilst all photographers desired to see the art progress of photography, it should never be forgotten that it was to scientific experimentalists artists must look for the power to progress. The delicacy, roundness, and many excellent qualities which were now common in photographs, were a few years ago scarcely attainable. During the old regime of iodized collodion and pyrogallic acid, hard black and white pictures were the rule; and when the chemical conditions were such as yielded those results, artists might labour in vain. The use of bromides and iron development had placed a new power in the hands of the artists, the results of which we found in better and softer pictures. He might here suggest that it was desirable that the experimental committee should resume its labours, and especially suggested for its attention the subject of a dry process which should be as good as wet collodion.

Mr. WALL suggested that an instantaneous dry process would put a great power in the hands of the portraitist, who would then have a plate ready for exposure at any moment. The great superiority of the higher class of portrait painters over others did not generally consist in the superiority of their drawing or colouring, so much as in their power to embody character. Such men would think nothing of engaging the sitter for half an hour or an hour in conversation, watching for the right expression before they touched the canvas.

Mr. SIMPSON remarked that, valuable as the suggestion might be, he feared it was scarcely applicable to photography, especially as now practised. The tendency of the day was to rapid production in large quantity. He feared that any suggestion for the art progress of photography, which was inimical to its commercial success, would scarcely obtain much attention. Again, as to the use of dry plates, however valuable instantaneous dry plates might be to the tourist, they would scarcely be used under any circumstances by the portraitist. The photographer who at all knew his business, had, in the wet process, such a safe, certain, ready, rapid, and satisfactory power, that he would not be likely to exchange it for the inevitably lengthy manipulations of the most perfect dry process. As to having a plate always ready, that was easily managed. In one of the largest and best managed portrait establishments in London, which he knew, the custom was, during the season, for an operator to commence coating and exciting plates from the first thing in the morning until evening, without any inter-

mission, so that a wet plate was ready at any moment the artist might require it.

Mr. WALL thought that the commercial interests of photography should be subservient to its art progress.

Some conversation followed, in which the Chairman, Mr. Fry, Mr. Leake, and others, thought that no advantage would be gained by the use of dry plates in the studio, and that portraitists would never abandon the wet process. A desultory conversation on the possibility of keeping wet plates for twenty minutes or half an hour in the dark slide, during the arrangements of portraiture, followed, many precedents being quoted in support of the practice.

The Rev. F. F. STATHAM made some interesting remarks on the phases of photography, illustrated at the International Exhibition. He referred to the variety of style which might be introduced into portraiture—referred, for example, to the productions of the Dutch painters, in which portraits were produced as character pictures, so that they were interesting and valuable as works of art long after the individuals portrayed were forgotten.

Mr. SIMPSON had been reminded, by some remarks of Mr. Statham, in reference to card pictures of landscapes, of one he had just received from an anonymous correspondent, which he wished members to examine as one of the most perfect small pictures he had ever seen. It was a view of Edinburgh, from Calton Hill, in which every part of the foreground was most perfectly and brilliantly defined, and yet fine natural clouds were secured in the sky. He had no information as to how it was produced, except that it was on a Fothergill plate. He did not know by whom it was produced; but, from collateral evidence, he was disposed to attribute it to Mr. Archibald Burns, of Edinburgh, a well-known skilful Fothergill manipulator.

After some further conversation, Mr. FRY, at the call of the Chairman, said, that the able remarks of Mr. Statham had quite cut the ground from under him for further comment. There was first one subject to which he would refer. It would be within the recollection of members that, two years ago, he read a paper before this society, on printing in skies, and other forms of double printing, with a view to artistic effect. It met with some opposition, and was, in fact, manifestly a premature paper—one which photographers were not then ready for. He was very happy in being able to call attention to many prints in the Photographic Exhibition (which would open in a few days), in which photographers, of undoubted skill and reputation, had adopted the system referred to, and with manifest advantage to their pictures.

The CHAIRMAN proposed that Mr. Simpson be requested to ascertain the artist who had produced the charming little card landscape they had been examining, and the terms at which a sufficient number could be procured, in order that each member of the society might have in his possession a picture which might serve as a standard for imitation. This was carried by acclamation.

Mr. LEAKE called attention to two pieces of lead pipe, quite eaten through by the vapours of acetic acid.

Mr. STATHAM suggested that the society should keep a Desideratum Paper, on which should be entered, from time to time, a note of all the especial wants which occurred in the art. Such a memorandum would preserve a record before the eye, of things which would often otherwise be forgotten.

It was announced that, at the next meeting, Mr. George Price would read a paper on the Theoretical Principles of Positive Printing. The proceedings then terminated.

The International Exhibition.

REPORT OF THE JURY ON PHOTOGRAPHY AND PHOTOGRAPHIC APPARATUS.*

THE PRINTING COMMITTEE.

CIRCULAR letters were addressed by the committee to photographers of experience and reputation, asking them to assist in the purposes of the inquiry by information and suggestions, and also by contributions of prints, with particulars of the method of producing them, in order that the fullest experiment and examination might be made. The results of this inquiry were furnished in the following Report:—

"Evidence of Permanence.

"The Committee have unquestionable evidence of the existence of Photo-

* Continued from p. 21.

graphs which have remained unaltered for more than ten years, prepared by salting plain paper with a chloride, afterwards making it sensitive with either nitrate of ammonio-nitrate of silver, fixing with a freshly-made solution of hyposulphite of soda and washing in water; also of positives produced by Mr. Talbot's negative process.

"They have not been able to obtain evidence of photographs having been prepared at all upon albumenized paper, or coloured with a salt of gold or fixed with "old hypo" so long ago as ten years.

"They have, however, ample evidence of the existence of unaltered photographs so prepared, five, six, and seven years ago.

"They have not found that any method of printing which has been commonly followed, will necessarily produce fading pictures, if certain precautions be adopted, nor have they evidence that any method which has been adopted, will not produce fading pictures unless such precautions are taken.

"Causes of Fading.

"The most common cause of fading has been the presence of hyposulphite of soda, left in the paper from imperfect washing after fixing.

"The Committee think it right to state, that they have been unable to find any test to be relied upon, which can be used to detect a minute portion of hyposulphite of soda, in the presence of the other substances which are obtained by boiling photographs in distilled water, and evaporating to dryness; yet they have no doubt of the truth of the above statement, from the history given of the mode of washing adopted.

"The continued action of sulphuretted hydrogen and water will rapidly destroy every kind of photograph; and as there are traces of this gas at all times present in the atmosphere, and occasionally, in a London atmosphere, very evident traces, it appears reasonable to suppose that what is effected rapidly in the laboratory, with a strong solution of the gas, will take place also slowly, but surely, in the presence of moisture, by the action of the very minute portion, in the atmosphere.

"The Committee find that there is no known method of producing pictures which will remain unaltered under the continued action of moisture and the atmosphere in London.

"They find that pictures may be exposed to dry sulphuretted hydrogen gas for some time with comparatively little alteration, and that pictures in the colouration of which gold has been used, are acted upon by the gas, whether dry or in solution, less rapidly than any others.

"They also find that some pictures which have remained unaltered for years, kept in dry places, have rapidly faded when exposed to a moist atmosphere.

"Hence it appears that the most ordinary cause of fading may be traced to the presence of sulphur, the source of which may be intrinsic from hyposulphite left in the print, or extrinsic from the atmosphere, and, in either case, the action is much more rapid in the presence of moisture.

"Mode of Mounting Photographs.

"The Committee find that, taking equal weights, dried at a temperature of 212°, of the three substances most frequently used, viz.: gelatine, gum, and paste, the latter attracts nearly twice as much moisture as either of the former; and, as in practice, a much smaller weight of gelatine is used than of gum, gelatine appears to be the best medium of these three; and the Committee have evidence of fading having, in some cases, been produced by the use of paste.

"In illustration of some of the circumstances alluded to above, the Committee think it well to mention some instances of prints at present in their possession.

"Out of several prepared together in 1844, three only are unaltered, and these were varnished soon after their preparation with copal varnish.

"Half of another print of the same date was varnished, and the other half left; the unvarnished half has faded, the varnished remains unaltered. Three pictures were prepared in 1846, all at the same time, with the same treatment: when finished, one was kept unmounted; the other two were mounted with flour-paste at the same time, one of these latter having been first coated with Canada balsam; at present, the unmounted one and the one protected with the balsam are unaltered, whereas the other has faded.

"A picture prepared in 1846 was so exposed that the lower part of it became wetted with rain; at present the part so wetted has faded, while the rest of it remains unaltered. Several pictures were prepared and mounted about ten years ago, and kept in a dry room for about three years without any change, after which they were placed in a very damp situation, and then faded decidedly in a few months.

"The Committee propose very shortly to actually test the durability of the various modes of printing, by exposing pictures to different treatment, and they have been fortunate enough to obtain a grant of space for this purpose from the Crystal Palace Company.

"The Committee make the following suggestions, arising out of the above Report:—

"1. That the greatest care should be bestowed upon the washing of the prints after the use of hyposulphite of soda, and for this purpose hot water is very much better than cold.

"2. The majority of the Committee think that gold, in some form, should be used in the preparation of pictures, although every variety of tint may be obtained without it.

"3. That photographs be kept dry.

"4. That trials be made of substances likely to protect the prints from air and moisture, such as caoutchouc, gutta-percha, wax, and the different varnishes."

CARBON PRINTING—THE DUC DE LUYNES' PRIZE.

The methods of printing, toning, and fixing photographic pictures had up to this period not undergone much modification since their original discovery.

An image formed by the action of light upon paper prepared with the chloride of silver and fixed by means of a solution of hyposulphite of soda was found to be tolerably permanent, but its colour, a reddish brown, was unsuited to the purposes of pictorial effect. The addition of chloride of gold to the fixing solution aided in producing a variety of purple black and neutral tints, which were much more agreeable and satisfactory. This addition, however, introducing an element of decomposition in the fixing solution, was thought by many to increase the chances of fading. To avoid this difficulty a new method has been proposed, in which the toning of the print by means of a solution of gold is conducted prior to the process of fixing by means of hypo-

sulphite of soda. This was considered an important step in the securing of permanency, and it is believed that photographs, produced with an intelligent regard to known laws, and preserved with a care due to works of art, may be considered as permanent. Although it is an undoubted fact that the phenomenon connected with the printing, toning, and fixing of photographs, so as to secure under all conditions entire permanency, still presents more points for anxious examination and inquiry to the scientific photographer, yet the fact that there are in existence many photographic prints which have remained unchanged for upwards of twenty years, proves, beyond all doubt, that the causes of fading are not inherent, but accidental, and that they only require to be better understood to be entirely removed.

The desire for absolute certainty as to the permanency of prints from photographic negatives has led to many attempts to substitute other substances for the salts of silver usually employed.

In the year 1856 a French nobleman, the Duc de Luynes, in order to give an impetus and a definite purpose to efforts in this direction, offered a prize of 2000 francs for the most perfect process of printing in carbon, two years being allowed for competitors to complete their researches in.

It was agreed that carbon being of all substances known to the chemist one of the most stable and unaltered, it was manifest that if it could be used for producing the blacks of the photographic design, the same guarantees would then be obtained for the permanency of photographs which exists for the stability of printed books and engravings, and that such a consummation was all that could be hoped or desired. Several competitors responded to the appeal thus made, and a commission of gentlemen was formed in the year 1858 to report upon the processes submitted by the respective claimants for this prize.

The report was made in the year 1859, in which it was stated that no process submitted at that time was sufficiently perfect to merit the entire award. The nobleman who had instituted the competition then intimated his willingness to allow the offer to stand over for three years more, at the same time allowing the commission to divide the 2000 francs amongst the various gentlemen who had best contributed to the end in view—the production of permanent prints. Two gold medals, each of the value of 600 francs, and two silver medals, each of the value of 400 francs, were then awarded. A gold medal was given to M. Poitevin, as the originator of the first idea upon which carbon processes were based, viz., the peculiar action of light upon a combination of salts of chromium and organic matter. A gold medal was awarded to Messrs. Divanne and Girard for their investigations into the causes of instability in silver prints. A silver medal was awarded to Messrs. Garnier and Salmon, for a process of printing in carbon. The other silver medal to Mr. Poncey, an Englishman, for a similar process. The commission appointed to decide upon the second competition have recently made their report, and have awarded to M. Poitevin the prize of 2000 francs, and an additional medal, value 600 francs, to M. Farzier for his process. Specimens of each of these artists' works are in the Exhibition.

Notwithstanding the fact that great progress has been made, much still remains to be desired, and a further prize is again offered by the Duc de Luynes, to be awarded in 1864, and it is still open to competition.

In referring to this interesting portion of the history of the art, and according high honour to the nobleman by whom it was initiated, there remain one or two remarks to be made.

It would be manifestly beside the purpose of this report to enter into an examination of the claims for priority of invention made by various experimentalists; but it is impossible to refer to the matter without drawing attention to the fact that the germ of all these processes was the discovery of an Englishman. In May, 1839, Mr. Monge Pouton communicated to the Royal Scottish Academy of Arts his discovery of the action of light upon paper, prepared with a solution of bichromate of potash, a discovery upon which the carbon processes and the majority of the photo-engraving and photo-lithographic processes have been based.

(To be continued.)

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 14th January, 1863.

A PROCESS for obtaining paper positives and negatives, with nitrate of silver alone, is announced by M. Gaumé, of Mans. He employs a nitrate solution of the strength of 4 or 5 per cent., upon which the paper is floated 4 or 5 minutes, then dried in a dark place. The exposure in the camera must be about 20 or 30 seconds for negatives, and several minutes for positives. Both negatives and positives are developed with gallic or pyrogallic acid, without the addition of silver. They are toned with chloride of gold, and fixed in rain water. The same results may be obtained upon albumenized paper, without iodide or chloride, and the proofs are remarkable for their delicacy. By this process, therefore, pictures are obtained with nitrate of silver only. M. Regnault considers that it will be more prudent to fix with ammonia, as recommended by M. Humbert de Molard.

Mr. Maxwell Lyte has pointed out a cause of fading in paper positives which has not hitherto been noticed, viz.:—the presence of sulphur in the Bristol boards, &c., used as mounts. In paper manufacture, the pulp is bleached by the action of chlorine, and to remove all traces of this bleaching agent, manufacturers frequently put into the vat,

under the name of *anti-chlor.*, a certain quantity of hyposulphite of soda. But this substance acts only on condition of being decomposed by the chlorine, and the products of the decomposition of the hyposulphite of soda, eminently unstable, always cause the liberation of a certain quantity of sulphur, which remains in the pulp, sometimes in so considerable a quantity that it is literally possible to extract the sulphur by sublimation. Besides the sulphur, there is always a slight excess of hyposulphite of soda, and it need cause no surprise when we see proofs mounted upon certain kinds of cardboard, show the fatal yellow stain, while other proofs, prepared under exactly similar conditions, remain intact if not mounted.

Therefore, in mounting proofs we encounter numerous causes of fading, either from the presence of free sulphur, or of an excess of hyposulphite of soda, or of chlorine, or of hypochlorite of lime, or even from the chloride of sodium, resulting from the decomposition of the hyposulphite of soda by chlorine.

We may easily detect the presence of hyposulphite of soda, chlorine, and the chlorides, by the following experiment:—

Beat up a piece of the suspected card-board in a porcelain or glass mortar with distilled water; to one portion of the filtered liquid add a crystal of nitrate of silver, which in the course of a few minutes, gives, when sheltered from the action of light, a yellow, or even a black, precipitate, if any traces of hyposulphite of soda be present. In the other portion of the liquid, previously acidulated with a little nitric acid, and boiled, also put a crystal of nitrate of silver, which, if chlorine or chlorides be present, gives a white precipitate of chloride of silver.

The detection of free sulphur, rather more difficult, is made by attacking the paste of the card-board with *aqua regia* entirely free from sulphuric acid, after the evaporation of the greater part of the liquid, and the incomplete saturation of the excess of acid by a little ammonia. Then add some distilled water, and filter; the presence of sulphuric acid in the clear diluted liquid, is recognised by chloride of barium.

A successful mode of treating the ashes arising from the burning of photographic paper clippings, &c., consists in the following:—the papers are first burned in a laboratory furnace; the ashes, left undisturbed for several hours, gradually consume all the carbon; they are then collected together, weighed, and melted without any other treatment. After some comparative experiments made upon 150 grains of ashes, the following proportions have been adopted:—

Ashes	10 parts.
Carbonate of soda (dried)	5	"
Pure silica sand	2	"

The addition of the silica appears indispensably necessary. We thus obtain a very fluid nitreous slag, with a comparatively low temperature. The grains of silver are easily collected together, and the very compact matter thus obtained dissolves perfectly in nitric acid diluted with its own volume of water. The gold mingled with the silver remains in the capsule in the form of a black powder.

Generally the ashes of the refuse papers of the operating room arising from filtering papers, clippings, &c., yield from forty to fifty per cent. of their weight of silver.

M. Gaudin, the editor of *La Lumière*, has published his Photographic Programme for the current year, in which he points out the subjects deserving the especial attention of photographers, and to the investigation of which he intends devoting himself. First in importance stands a *sensitive dry collodion*. The defect in this is due entirely to the cohesion the collodion acquires in drying, which transforms it into a horny substance of a greasy nature, which does not permit aqueous liquids to penetrate it to react upon the impregnated iodide of silver it contains. Collodion which has never ceased to be wet, may be regarded as forming spongy film composed of extremely fine fibres interlaced, and acting as a support to the iodide of silver. This is, at least, what

takes place in employing the ordinary silver bath of eight or ten per cent., with a weaker bath, of two per cent. for example; the iodide of silver is produced only on the surface of the collodion, forming a continuous pellicle; unfortunately this pellicle does not adhere, and becomes detached in spots, leaving the collodion bare, and consequently perfectly transparent. From a present point of view, this is to be regretted, for we well know that a sensitive coating, which can be applied to the whole surface of the collodion, will not be protected from the developing agents by the drying of the subjacent collodion.

From this it is clear that a dry collodion composed of perfectly rectified ether and alcohol; will be less porous and less sensitive than a collodion prepared with alcohol and ether a little aqueous. In drying the first will become compact and nitreous, while the second will be very porous; but also, its cohesion will be feebler, and it will scarcely bear the numerous operations consequent upon developing the pictures, unless it be placed on a glass-plate previously covered over its entire surface with a very dilute coating of albumen; a simple edging of albumen being insufficient in this case.

Glycerine in collodion appears to act in the same manner as water, but it is probable, that in putting it on to a washed sensitized collodion, it acts like tannin, by lodging in its pores. As to inertness, and permanence of the humid state, it holds the first rank, and if we had not to fear the adherence of dust, it would, perhaps, be superior to tannin, as it carries with it a certain power of reduction, which is called into play every time the iodide has been impressed by light, however little, during the preceding operations.

The Developing Bath of Proto-acetate of Iron.—Thus far I have found nothing comparable to proto-acetate of iron for the development of negatives. The proto-nitrate is much too difficult to preserve, from its tendency to precipitate the silver in a white state. It is valuable for direct positives, but the pictures are always a little granulated, while the proto-acetate of iron, which gives, it is true, a yellow metallization, produces a delicacy equal to that given by pyrogallie acid. The great advantage to be derived from the employment of proto-acetate of iron, is that of producing in the negative a black proportionate to the intensity of the light, which has acted upon the collodion; an advantage which it does not share with any other developer. Sulphate of iron, for instance, never gives skies which can be printed uncovered, at the first pouring on, but require intensifying. During my latest researches, I have been prevented from employing the proto-acetate of iron which I had prepared, because it always produced a general inky blackness over the whole plate, without any picture; but I shall soon discover the cause of this singular obstacle, which is doubtless caused by some organic matter inherent to the products used in its preparation.

Preparation of Photographic Cotton by Nitrous Gas.—I have already made an experiment to prepare photographic cotton by the action of nitrous gas: the effect was *nil*. I ought not to have expected to succeed, for previously I had failed to obtain any result upon passing this gas through several folds of rag; but I did not think the intervention of water was necessary to this reaction; the idea occurred to me only during my last experiment. I have now no doubt that moistened cotton will produce the desired result; it would greatly surprise me if it did not. In the event of success, it is easy to perceive the great facility that would result in the preparation, on a large scale, of a product so extensively employed at the present time, and I see a means of obtaining it more easily and with less variable properties.

Mofication of Organic Substances, mixed with various Salts, under the influence of Light.—The mixture of alkaline bichromates, by which certain organic substances become insoluble by the action of light, is the first step on a boundless path. Quite recently it has been asserted, that any organic matter, the juice of walnut-peels, for instance,

becomes, without any addition to it, black and insoluble under the action of light. I have thought it necessary to notice this statement, which appears to me very extraordinary, because an operator asserts that he has obtained proofs by this means. For lack of walnut-peels, I have prepared a decoction of walnut leaves, without being able to recognize any photogenic property in this decoction when spread upon paper. Until proof is afforded to the contrary, I shall suspect that there is some error in this statement; but we must restrain our incredulity in remembering that even the illustrious Arago was too hasty in imposing limits to the power of photography.

Carbon Printing.—The highest aim of photography is to arrive at results in which durability shall rival perfection. In taking proofs with lamp-black upon ordinary paper, we seem to have attained this aim. Such, however, is not our opinion. It seems to be possible to obtain upon a steel plate, suitably coated, an engraving by the action of light solely, and to be able to print a small portrait with a black mineral ink, on asbestos paper with a suitable vitreous mixture, so that, after being subjected to a red heat, we shall possess indestructible pictures, so long as they are not exposed to the heat of a forge.

PHOTOGRAPHY ON CANVAS.

Ghent, Belgium, January 4th, 1863.

DEAR SIR,—In your number of January 9th, I find a letter from Mr. J. T. Lucas junior, by which he claims to have made perfect photograpis on canvas in March 1859.

Allow me Mr. Editor to give you a few dates relating to this matter.

It is, to my knowledge, that in 1855 or 1856, Mr. Charles Fontayne (of Porter and Fontayne, photographers, Cincinnati, O.) experimented on canvas coated with iodized albumen. I know of no particulars about it.

In April 1856, Mr. J. H. Tatum of Baltimore, M.D., patented a process which gave but indifferent results. The canvas was treated with alkali, then with chloride of sodium, after which it was silvered, exposed to light, and fixed with hypo. Finally flowed over with a very diluted solution of sulphuric acid.

In 1858, the exact date I cannot tell, Mr. Marinus Sanier communicated to the *American Journal of Photography* a process which I tried with success in the winter of the same year. The canvas was cleaned with a solution of cyanide of potassium and well rinsed, then coated with diluted iodized albumen, sensitized with aceto-nitrate of silver, developed with gallic acid, and fixed with hyposulphite. The great drawback to this process is, that a thin film must be used or it will crack after painting, and a thin film gives less success than a thick one. This evil was remedied by substituting gelatine for albumen. From the moment I made this alteration, I worked with constant success.

I may at a future time, and with your permission, give you a description of the process in all its details. Until of late, having made a special business of photography on canvas, I considered the process as a *trade secret*, and have only communicated it to a few friends.—Yours, respectfully,

CHARLES WALDACK.

From Cincinnati, Ohio U. S.

[We shall have much pleasure in learning the details of Mr. Waldack's method of working on canvas.—ED.]

THE PRESERVATIVE QUALITIES OF CAOUTCHOUC.—We quote the following interesting notice from the *Chemical News*:—*Wood for Ship Building.*—Professor Crace Calvert is now making an investigation for the Admiralty of different kinds of wood used in ship building. It appears that the professor is at no loss to explain why so many of the fleet of recently built gun-boats became rotten and others escape untouched. He finds the goodness of teak to consist in the fact that it is highly charged with *caoutchouc*; and that, if the tannin be soaked out of a block of oak it may then be interpenetrated by a solution of *caoutchouc*, and thereby rendered as lasting as teak. Of the durability of teak there can be no question.

To Correspondents.

* * * Wanted, for full prices, or in exchange, the following numbers of the PHOTOGRAPHIC NEWS:—76, 80, 81, 91, 101, 197, 198, 200, 202, 203, 213, 214, 215, 216.

F. P.—It is by no means absolutely necessary that transparencies for the magic lantern should be taken on albumen. The advantage claimed over collodion is greater brilliancy, sharpness, and richness of tone. By skillful manipulation, and careful choice of process, collodion transparencies may be made to imitate those on albumen very closely. Those who prefer the tone of albumen will find the tannin process gives very similar results. If you wish to try the albumen process you will find various articles with full details in the back volumes of the NEWS. We can only briefly state here that the albumen is prepared with an iodide and a bromide, the same as collodion, the plate is coated and allowed to dry, then excited in a bath of aceto-nitrate of silver, washed and again dried, and then exposed. With dry plates, printing by superposition, as in paper printing, is a common practice, giving a short exposure and then developing; no toning is needed with albumen. If wet collodion and camera printing be used—and excellent transparencies may be so produced—then the negative must be placed in a groove of a box or a camera so that no light shall enter the camera or reach the sensitive plate except through the negative. Various articles on transparencies appeared in our last volume.

H. P.—Your letter is not quite clear as to what part of the plate presents the "silvered" effect to which you refer. So far as we can judge from your description it is from abnormal reduction, or fogging, and may proceed from a variety of causes, which, without seeing the result, we cannot certainly point out. It may be over-need collodion, or diffused light, or the bath. Most probably the latter. Try adding a little bicarbonate of soda in solution, until a precipitate begins to be formed. Then expose a few hours to light, filter, and add a little nitric acid. If the defect arise from the bath, this will most probably cure it. 2. The time required for fixing prints in a fresh solution of hyposulphite of soda, one ounce in five of water, is about a quarter of an hour or twenty minutes.

H. S.—The defect is an unusual one, or, rather, it has presented itself in an unusual degree. It is probably due primarily to the quality of the paper, which is unusually absorbent. The defect arises from partial absorption and unequal drying of the albumen, the portion not dried then flowing over that which is dried, and causing what are technically called by albumenizers, "curtains." Newness of the paper, the size not being thoroughly hardened, will cause it. The albumen, in this case, partially dissolves the size, and the two mingling together produce the unequal surface. The extremely absorbent character of the paper is shown by moistening the back; the moisture is absorbed and disappears at once. The sample sent you tastes strongly of the salt, at the back, showing that it has been thoroughly absorbed. This would readily account for the difficulty. The suggestions we may make are: use undiluted albumen, and add neither ammonia, nor anything else but the chloride; see that the paper is thoroughly dry; float a very short time, scarcely more than drawing the sheet over the surface of the albumen without allowing it to remain at all; try some of the recent suggestions for making the paper waterproof previous to albumenizing. Or get another older, harder, less absorbent paper.

SIGILLI.—We will try your bath and report next week.

A. B. C. will oblige us by communicating his address, and the terms upon which he can supply a few dozens of the exquisite view of Edinburgh from Calton Hill, with any other particulars. See our report of the last South London Meeting.

D. A. proposes to coat plates with collodion and allow them to dry, subsequently exciting, &c., in the field, for use. We fear very little would be gained in convenience, and something would certainly be lost in several ways.

L. E. W.—You can register and secure the copyright of a photograph of an oil-painting; but that does not interfere with the right of others to copy the painting if they have an opportunity. It only secures your photograph from being copied.

E. W.—The article to which you refer contained an extract from Mr. Sutton's Notes. It was he who proposed to send a sample of the paper, in which he was interested, to readers of the Notes. We believe that such a sample was given with the Notes of January 15th.

MICHAEL LOAM.—The manipulations in making collodion are best effected in the following order:—First, add half the alcohol to the cotton, and let it get well saturated with it; then add the ether, and shake until all the cotton is dissolved. Now, let it stand for a day or two, and either decant or draw off with a siphon the clear collodion from the residue. In the remaining half of the alcohol dissolve the iodides and bromides, if necessary, grinding them with a little alcohol in a mortar of glass or Wedgwood ware. When dissolved, filter; and then add the proper quantity of the filtered solution to the clear collodion.

H. GOBLE.—We cannot recommend you to tone and fix in one bath, by the old method. But, if you do so, always use the solution fresh made, thus:—1 ounce of hyposulphite of soda, 1 grain of chloride of gold, and 4 ounces of water, adding a piece of borax the size of a walnut for each pint. Do not add silver, or anything else. Or you may use the bath of *sel d'or*, thus:—1 grain of gold, three grains of hyposulphite of soda, and 4 ounces of water, afterwards fixing in a fresh strong solution of hyposulphite. 2. The backgrounds in Messrs. Southwell Brothers' studio, are generally of a somewhat dark grey.

A SUBSCRIBER FROM THE BEGINNING.—We believe the best lenses in the world are made by the two English makers you name, and their lenses are chiefly used by good London artists. We do not know any foreign lenses which surpass them.

A NOVICE ON THE CONTINENT.—The only journal of general character devoted solely to chemical science is the *Chemical News*, edited by Mr. W. Crookes, published weekly, price 4s., at No. 1, Wine Office Court, Fleet Street. There are monthly journals, which are simply organs for recording the transactions of the societies to which they belong, such as the *Pharmaceutical Journal*, monthly, 1s.; and the *Journal of the Chemical Society*,

monthly, 1s. The *Philosophical Magazine* contains, occasionally, some chemical articles, monthly, 2s. 6d. There are several good chemical journals published on the Continent, amongst which we may name the *Comptes Rendus*, and the *Reperoire de Chimie, Pure et Appliquée*. 2. Black varnish is sometimes used for stopping out skies. If you cannot purchase it ready, brunswick black, diluted with turpentine, will answer. Water colours, such as lamp black ground in gum water, are sometimes used. We don't like stopped-out skies.

L. M. B.—Your picture is exceedingly creditable for an amateur. The chief improvement it would bear would consist in a trifle more exposure and less intensifying, this would make it a little softer. We are glad you profit so much by reading the NEWS. A little more practice will make you perfect.

C. F. W.—The book was sent. We shall look forward with interest for your promised communication.

GILLARD.—A report on your glass in the "Scientific Gossip." We have not yet seen any of the pictures referred to, but we have good reason to believe they are not photolithographs. We have been told they are vile diminutive photographic copies. But we confess that we, in common with others, are puzzled by the advertisement.

JOHN MARTIN.—The glass was so broken that we could not form an opinion of it. 2. The difference between the samples of acetic acid is that one really is glacial, and should freeze at 50°, the other is not, but is largely diluted and possibly impure. 3. We do not see any reason why photographs taken with the pistolgraph should not answer for the oxy-hydrogen microscope if care be taken regarding the definition. 4. We do not know which rolling-press you especially refer to, but, as a rule, the larger ones give a heavier pressure. We believe some of the smaller ones answer very well.

A CONSTANT SUBSCRIBER.—There is no obligation upon persons publishing registered photographs to have the fact announced on the print, but we think it would be advisable to do so. The mere fact of printing "registered" upon the photograph would be no proof, however, that it was copyright. The presumption is, that the copyright of all photographs belongs to somebody, whether protected by regular course of law or not, and that it is the duty of persons wishing to copy them for their own purposes to ascertain how far they are permitted to do so, or otherwise run the risk of piracy. The only method of ascertaining whether a picture is protected or not, is to enquire of the publisher, or search at Stationers' Hall, on paying the proper fee.

CHELTENHAM.—Your cards appear to have stood very well, but an exposure during four months is not a very severe test. The chief improvement required is a little more brilliancy and better definition. You will find valuable printing formulae in our ALMANAC, just published. You will find instructions for ammonia-nitrate there, and also repeated in the last volume.

AMICUS.—In the case stated, where an operator works for you at a regular salary, using your chemicals, &c., on your premises, &c., there cannot be a doubt about it that the negatives, taken belong to you, unless there were a direct bargain to the contrary. The fact of the camera belonging to the operator does not in any way give him a claim to the negatives.

R. M.—We are obliged by the interesting paragraph. The plan of taking a photograph in several pieces, and joining them, is not, however, new.

XENOPHON.—It is unquestionably philosophically right to reverse the lens in enlarging, so that the transit of the rays through the lens shall be after the same manner as in ordinary operations for which the lenses are constructed. We have not, however, noticed any practical disadvantage from neglecting to reverse.

THOS. COLLINS.—In Mr. Warner's remarks in reference to securing clouds with Dallmeyer's No. 1, triple, on a plate 10 by 6, there is no discrepancy. The No. 1 triple gives a circle of light twelve inches in diameter; and we have seen respectable pictures on a 10 by 8 plate taken with it. Many operators work on a plate 10 by 8 with this lens, and subsequently cut the print to whatever dimensions may suit it best. 2. We believe it an error to suppose that the triple, or ordinary double lenses, give less brilliancy than single lenses. Some of the most brilliant pictures we have ever seen have been taken with the triple. As for double lenses there cannot be a doubt as to the brilliancy of the image. 3. We have found no disadvantage from the use of an ebonite bath. 4. The sixth volume of the *Chemical News* has just been issued, we believe. It is published in Wine Office Court, Fleet Street.

PERPLEXITY.—The most palpable error in your operations, is the use of 20 drops of nitric acid in an ounce of developing solution. Try again with 2 drops. Your collodion being old and red may be insensitive. Try some fresh. Also try a better light if you can, the open air for instance. It is very probable from the appearance of the positive, which arrived in fragments that your bath is out of order. Make a solution of bicarbonate of soda, 10 grains to an ounce of distilled water; then add a few drops at a time to your bath until a precipitate begins to fall. Now place the solution in sunlight for a few hours; then filter, and add a drop of nitric acid to each four ounces of solution. It will probably work bright and clean, if not, add about as much more nitric acid, then try. Let us know of the result, and we will, if necessary, try to help you further.

TYRO R.—You will easily ascertain if you have too much of the roof over the head of the sitter darkened, by bringing him forward a little and trying a picture. We should be disposed to remove the yellow calico at the sides entirely. The general arrangements seem good. We could judge better by seeing a picture taken with the unsatisfactory arrangements.

Henry Regnier, Charles Derby, J. W., M. C., and several other correspondents in our next.

PHOTOGRAPHS REGISTERED DURING THE PAST WEEK.

By MR. JOHN STUART, 120, Buchanan Street, Glasgow.

1. Right Rev. Bishop Murdock.
2. Rev. James Knox.
3. Rev. James McNaught.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to the Office, 32, PATERNOSTER ROW, LONDON.

EXCESS OF DENSITY IN IODIDE OF MERCURY NEGATIVES.

WE are enabled to relieve the minds of many of our readers from an apprehension, which has been felt of late by photographers using bichloride of mercury and iodide of potassium, for intensifying their negatives. This process has been very extensively used during the last year, or since the method of using it, with great success, as practised by the late Mr. Lacy, was published in our columns. During the past summer a conviction has been gaining ground that the effect produced was not permanent. The deposit of iodide of mercury, in combination with the silver image, was found to darken gradually under the action of intense light, so that if the right amount of intensity were gained at first, the negative gradually became hard during the course of continued printing.

All photographers are familiar with the fact that a silver image, treated with bichloride of mercury, has a tendency to darken under the action of light. Neither the salt of mercury alone, nor the reduced silver, darken by light; but it is probable that some trace of chloride of silver is formed upon which light acts. Iodide of mercury alone, in like manner, is not darkened by light, but the deposit, formed by its action upon a negative, is found, under some circumstances, to change under the action of light and become darker. What is the precise nature of the change is uncertain; nor has the fact itself excited much attention until recently. Mr. Lacy was in the habit of urging, as an advantage attending the process, that the negative became a little more brilliant, after once or twice printing, the sparkling points of high light becoming more pronounced and definite. In his experience, however, the negatives did not become hard. Mr. Hughes, who became his successor in business, found, on printing some thousands of copies from the royal negatives of Mr. Lacy, that they became, in process of time, so much denser and harder that they were comparatively useless.

The subject has several times, recently, been discussed at the South London Society, where the evidence on the subject has been somewhat discrepant and varying. Mr. Blanchard has held that this change only took place when pyrogallic acid and silver, as well as bichloride of mercury and an iodide, had been used in intensifying, and has maintained the idea that it was to the presence of some trace of iodide of silver the darkening was due. Mr. Harman, and some others, had found the darkening proceed in the course of continuous printing, where bichloride and iodide only were used. The discrepancy of experience was sufficient, however, to throw doubt upon the value of the process, and excite lively apprehensions as to the ultimate fate of many valuable negatives already intensified by the method in question.

We are now able to announce a remedy for the evil—a means of restoring all such negatives which have become hard to their pristine softness and delicacy. We are indebted to Mr. Jabez Hughes for the information, the discovery having been made, accidentally we believe, in his

studio at Ryde, which enables him to obtain soft and detailed prints from valuable negatives which had been put aside, as giving hopelessly hard and unsatisfactory prints. The process of restoration simply consists in *roasting* the negative—holding it before a brisk fire until it becomes very hot. Whatever might be the precise cause of the evil, it appeared to result from a molecular change, the increased density did not arise from an aggregation of deposit, as in the usual processes of intensifying. The application of heat appears again to induce a molecular change, restoring the image to its original softness. We have not had opportunity of putting this experiment to the test ourselves, but have the assurance of a gentleman, vitally interested in the question, and accustomed to careful observation, that the remedy proposed is a valuable and trustworthy fact.

THE PHOTOGRAPHIC EXHIBITION.

SECOND NOTICE.

A MORE careful examination of the contribution at this year's exhibition, confirms all our first impressions, both as to general excellence and particular superiority. And we may add regarding the hanging, that we do not remember to have visited any exhibition in which a more pleasant effect was presented by the ensemble: there is a harmonious completeness in the general arrangement which satisfies the eye; the spotty scattered effect so common in such exhibitions, being fortunately avoided.

The first picture in the catalogue is an enlargement from a small negative by Mr. Ponting, of a beach scene. It is one of a similar class to several sent by Mr. Ponting to the International Exhibition. It is scarcely quite satisfactory, being wanting in force; it is nevertheless very meritorious for its pictorial effect, and is remarkable for its singular resemblance to a lithograph. Possessing many of the same beauties and faults are the contributions of Mr. Lyndon Smith. They are for the most part well chosen scenes—soft, detailed, and full of atmosphere—but they are so low in tone and wanting in power, that, being amongst more brilliant prints, they suffer by the comparison. His present contributions consist chiefly of Welsh scenery, and many of them are charmingly picturesque. The entrance to Llanberis Pass, (No. 13), is a very fine composition, and only wants vigour to be a fine picture. It is quite possible that, viewed alone, these pictures may be very good indeed. It is by juxtaposition with pictures possessing more contrast that they seem weak.

We next find a series of views of Osborne and other places in the Isle of Wight (Nos. 2 and 3). These are distinguished by clean bright photography, and in some instances very good composition; but there is perhaps, in some, a little hardness and want of atmosphere. The cabinet size, produced by the No. 1 triple lens which Mr. G. W. Wilson has rendered popular, is selected for these pictures, and is well suited to the class of views delineated. Very similar in character to the pictures of Mr. Rouch are those contributed by Lieut.-Col. the Honourable Dudley F. de Res (Nos. 14

and 74). These consist of various views at Windsor and Frogmore, and of the ruins of Grey Abbey, County Down. Some of these have a little tendency to hardness and want of atmosphere. A few clouds, or even a tinted sky, would have been a material improvement.

The bulk of the portraiture and figure photography is collected in one room distinct from the landscapes. For the purpose of varying the monotony, however, a few portraits and figures are hung amongst the landscapes, and in giving a detailed notice we shall proceed in consecutive order according to the catalogue, without reserving such portraits for a place in their own classification.

A couple of studies by Mr. H. P. Robinson, "The May Gatherer" (No. 5), and "The May Queen" (No. 6), are very charming. "The May Gatherer" is a pleasing rustic girl reclining on a grassy knoll, with a heap of hawthorn blossom. The position is graceful and natural, and the composition and photography both good, whilst the keeping of the sentiment is admirably preserved. "The May Queen" is a vignettted head of a sweetly simple and winning village girl, with a wreath of May blossoms entwined around her head. The photography is very good, the picture soft, round and beautifully modelled; but it is the charming expression, and wonderfully beautiful rendering of the eyes, which attracts attention most. We have seen a copy with the lines from Tennyson's "May Queen" appended, which the picture appeared admirably adapted to illustrate:

"There's many a black, black eye they say,
But none so bright as mine."

Altogether we might take this as a very satisfactory embodiment of "Little Alice."

The next subject-pictures which come under our attention are also executed in Leamington, and are by Bullock Brothers. The most striking and ambitious of these is the "Footsteps of Angels" (No. 20). In examining such a picture, the verdict given will much depend on the preconceived notions of the critic as to the legitimacy of the effort to make a picture by photographic means. Those who deride the attempt will chuckle over certain shortcomings here, as evidence of the inherent unfitness of the art to illustrate a poetical idea, or produce a picture with a story. We, who have always maintained the art-power of photography, and the legitimacy of every effort to develop its pictorial capabilities, examine such a picture with much interest, and regard its shortcomings with leniency. The picture fills nearly a whole sheet of paper, and the photography is decidedly good. The general effect as a picture, and the composition, are also good. The idea to be illustrated is that expressed in Longfellow's pretty little lyric, from which the title of the picture is borrowed, and which many of our readers may remember. The time is evening:—

"When the hours of day are numbered,
And the voices of the night
Wake the better soul that slumbered,
To a holy calm delight;

Then the forms of the departed
Enter at the open door;
The beloved, the pure hearted,
Come to visit me once more."

An elderly gentleman sits in an apartment lighted only by the fire; and, kneeling at his feet, is a female figure, intended, we presume, to represent the "Being beautiful," the departed love, referred to in the after lines. It is in this figure the chief failure is found; the choice of a model has been especially unfortunate, as the figure and face are not of that light, delicate, fragile, or refined type, which is suggestive of a disembodied state, and especially of the "messengers divine" referred to. As suggestion, not representation, is the only possibility in regard to such an idea, the selection of a suitable model was of vital importance, and especial care should have been taken to secure one with as little of material mould as possible. Again, the treatment of the figure is defective. There is nothing shadowy or indefinite here; the form is as essentially mundane and palpable as that of a figure still in the flesh. The pictorial

treatment of things unseen and immaterial must necessarily be more or less conventional, and all we can demand is that they shall in some way or other suggest the notion of disembodiment. It may be a dimly defined "shade," or a "luminous shadow," or it may be that uncertain substance of which Milton speaks—

"If substance might be called what shadow seemed,
For each seemed either ———"

But we want the idea suggested by the presentment in some way. This figure is very real, and an arm which is extended, unrelieved by any reflected light, is very black. Photography possesses resources for giving the air of immateriality we demand, and in such a case they should have been used. The effect of the firelight is very good, and for the most part the shadows in the deep gloom of the apartment are transparent and satisfactory. There are some lights for which we cannot quite account, regarding the fire as the sole source of light as the picture represents it. For instance, the bald head and the grey whiskers of the male figure are well lighted on the side opposite to the fire. On the whole the attempt is so bold, the result in some respects so good, and success missed rather by the want of a little more thought or effort than by the inherent difficulties in the way, that we have devoted more space to a consideration of its faults than we should have done if it had been a decided failure. And we intend these remarks rather as encouragement than censure. Two or three other large *genre* pictures, by the same artists, are less meritorious. A pair, "Mischief" and "Startled" (No. 47), do not express the ideas, and the models are ill chosen. "Confound the Screw" (No. 69), a musician tuning a violoncello, and perplexed by the difficulty of turning the peg or screw with one particular string, indulges in the expletive which gives the picture its title. Here the idea is well expressed, and the composition good; but the photography is a little coarse and hard.

The prints on resinized paper, from enlarged negatives, by Mr. Alfred Harman, will excite as much interest amongst photographers as any pictures in the exhibition, as they are decidedly the largest and best pictures of the kind which have been exhibited. The method of enlarging by two operations, first producing a transparency, and from that an enlarged negative, is one we have recommended for years. It has for some time been practised to a small extent. Mr. Samuel Fry has practised it for many years with great success. Mr. Vernon Heath and Warner have both, during the past year, given some popularity to the process by successfully applying and describing it. But none of the results that we have seen have been on such a large scale, and so entirely successful, as those of Mr. Harman. Here are four portraits, each about 22 inches by 17 inches, with accompanying prints from the card negatives from which the enlargement is effected. The portraits are chiefly standing figures, and some of them with various accessories; but in none, and in no part of them, do we find unsatisfactory pictorial definition, every part of each figure being as well defined as in the small prints, showing that no appreciable loss has been suffered in enlargement. No. 61 is especially fine, the composition being good, the image soft, round, vigorous, and well defined. The tone will probably be considered a little black by some, but the effect is very engraving-like, and will recommend the use of resinized paper—the sample used in this instance being, we understand, that prepared by Francis and Co., after the formula of Mr. Cooper. The print (No. 84) from an enlarged stereoscopic negative, printed on albumenized paper, scarcely strikes us as so delicate and pleasing as the others.

THE DISCOVERY OF THE METAL THALLIUM.

AMONGST the fruits already reaped from the valuable discovery of Messrs. Kerchoff and Bunsen, in reference to spectrum analysis, are, as our readers already know, three new alkaline metals—rubidium, cesium, and thallium. The

discovery of the latter of these, as our readers also know, is due to Mr. William Crookes, a gentleman to whom the photographic world generally is indebted for much information on the chemistry of photography. In the beginning of 1861, being engaged in spectrum examinations, Mr. Crookes discovered, in the flame of some residues of selenium, a single bright green line in a portion of the spectrum where such a line had not been seen before. Further investigations convinced him that this was a new element, which he shortly succeeded in isolating. The name of thallium was given to the new element—derived from a Greek word, signifying a young twig, the vivid green spectral line suggesting the name. The exact nature of the new body was not at first decided, but it was supposed to be a metalloid. In September of the same year, however, Mr. Crookes satisfied himself of its nature by obtaining the substance as a metal, which was shown to various persons in his laboratory.

Mr. Crookes seems destined to meet with injustice in regard to this discovery. In the International Exhibition, notwithstanding that he exhibited the metal and its compounds, and that his discovery of it was well known to the jurors, his name was not mentioned in the first published list of awards; whilst a French gentleman, M. Lamy, was rewarded with a medal for the discovery of new and abundant sources of the metal, the original discoverer of which was unnoticed. A proper and energetic exposure of this grievance brought some reparation. But recently Mr. Crookes has suffered another not less grievous injustice. M. Dumas, in a memoir just presented to the Academy of Sciences, denies to Mr. Crookes the discovery of thallium as a metal at all, and awards that honour to M. Lamy. The facts appear to us, however, to lie in a nut-shell. The credit is given to M. Lamy on assumed prior publication; and this publication of the metallic character of the new element is stated to have been made in a communication to the Société Impériale of Lille on the 15th of May, 1862. Now setting aside (as non-publication or insufficient publication) explanations and exhibitions to friends in the laboratory, here is the fact patent to all the world, that on the 1st of May, 1862, a case was exhibited by Mr. Crookes in the International Exhibition, containing samples of the metal and its compounds, in which it was distinctly labelled as a "new metallic element," and further described as a "heavy metal." Publication to a larger audience could not well have been made; and it is to be noted that the contributions of thallium to the International Exhibition by M. Lamy were not made until some time after it was opened. The comparison of the two dates appears to us to settle beyond a cavil the priority of the discovery; and whilst M. Lamy has had the good fortune and sagacity to discover abundant sources of the metal, it is clear that to an English investigator belongs the honour of discovering the element and deciding its metallic character.

PHOTOGRAPHIC CHEMICALS:

THEIR MANUFACTURE, ADULTERATION, AND ANALYSIS.

THE other compounds of alumina are of too slight importance to the photographic chemist to render any separate account of them of interest. The next element, the compounds of which demand our attention, is one which can scarcely be classed among the metals at all, although for the sake of convenience it is frequently so classified in chemical works. We allude to silicium, the oxide of which is the well known silica or rock crystal. In the natural state silica occurs under many forms; it is almost chemically pure under the form of fine white sand, immense quantities of which are brought from the Isle of Wight, for the purposes of glass-making. Another form of pure silica is known under the name of rock crystal. This is met with in hexagonal crystals, surmounted by hexagonal pyramids; the colourless transparent variety is largely used for optical purposes. Although not strictly coming under the category of a photographic

chemical, the properties of rock crystal are sufficiently interesting to our readers for us to devote a small space here to their description. Pure rock crystal possesses one great advantage over other solid transparent media, in being perfectly transparent to all the chemical rays of light. A photograph of the solar spectrum, taken with a complete quartz train—that is, with prisms and lenses of quartz—will show lines and bands in the spectrum three or four times as high as when taken with a glass train. In scientific researches upon the photographic action of light and colour, it is, therefore, necessary to employ rock crystal instead of glass wherever light has to be transmitted, as it has been shown by Mr. Crookes that the interposition of a piece of colourless glass, the hundredth of an inch thick, in the path of a beam of light, passing through a quartz train, is sufficient to cut off very considerable quantities of the chemically acting rays of light. By employing a meniscus lens of rock crystal for photographic purposes, very excellent results are obtained, owing to the large number of actinic rays which are transmitted by it on to the plate. A quartz lens can, however, be used only with a small aperture in front of it, as it cannot be achromatized without diminishing its transparency down to that of glass. Another objection to a quartz lens is its double refracting power, by reason of which the image formed by it is double when viewed under a high magnifying power. This defect may be obviated by taking care in the selection of the lens, or in having it cut in a particular direction, with respect to the axis of the crystal. When a beam of light passes through a crystal of quartz in such a way that it forms an angle with the axis of the crystal, it is doubly refracted, or split up into two rays slightly divergent. A lens cut from a crystal, in such a manner that the light would pass through, forming an angle with the axis, would therefore give a double image. When, however, a ray of light passes through a plate of quartz, parallel to the axis of the crystal, it is not doubly refracted; a lens, therefore, cut so that its axis coincides with the axis of the crystal, will only give one image.

It may be of use if we instruct our readers in a simple way of ascertaining whether a lens is made of quartz or glass. The latter is much the softer of the two, and therefore, by a comparison of one with the other, the sharp point of a file will show the difference without further trouble. This, however, is not a plan to be recommended, as it involves permanent injury to the lens. The plan we recommend is to employ polarized light for this purpose. A small tourmaline, which can be purchased mounted for a few shillings, is the only special apparatus required. A dark polished surface—such as French-polished mahogany, a japanned tray, black marble, or similar material—is placed on a table in front of a window. The photographer stations himself about four feet from this, so that the bright light from the sky is reflected upwards to him from the polished surface. The tourmaline is now brought up to the eye, and slowly rotated on its axis. As the crystal turns, the polished reflecting surface will be seen to become alternately light and dark; the tourmaline is kept in the position in which the reflecting surface appears darkest. The lens to be examined is now held between the tourmaline and the reflecting surface, and in its turn moved round on its axis. If the lens is of glass, no change will be produced by this movement; but if it is of rock crystal, it will become luminous during one part of its rotation, and then dark again, presenting a similar appearance to what took place when the tourmaline was turned round. It is possible, by this means, to ascertain in which direction, as regards the axis of the crystal, the lens is cut; and at the risk of not being clearly understood by some of our readers, we will endeavour to point out how this is discovered. Turn the tourmaline so that the reflecting surface appears quite dark, and move the lens on its axis until it appears luminous over its whole surface. Now turn the lens about sideways, so as to look through it in different directions diagonally, keeping the relative positions of top and bottom unchanged. As it is being moved about,

coloured spaces will appear on the luminous surface of the lens, which will pass over it in the order of the colours in the spectrum. On continuing to move the lens in the same direction as that which produced the colours, they will suddenly cease to appear, and will then be followed by another set of colours in the reverse order. The central position between these sets of colours is then to be returned to, and the experimenter will then be looking along the axis of the crystal from which the lens was cut. This may seem somewhat complicated and difficult to understand, but in reality it is very simple. After having once obtained the phenomena here described, any number of lenses can be tested one after the other, without spending more time than a few seconds for each. Anyone can obtain the appearances here noted by an attentive perusal of our description. Sometimes a quartz lens is found, in which the axis coincides almost perfectly with the axis of the lens, whilst at other times it will be found to be cut in such a manner that the two axes are almost at right angles to each other. Such a lens as this should, of course, be rejected.

We have already alluded to one property of rock crystal—its great hardness; this gives it an advantage over glass in cases where it is likely to be exposed to any rough usage, as it is very difficult to scratch. Another noticeable property is its power of conducting heat, being in this respect almost as good as a metal. A lens of rock crystal on this account is very quick in taking the temperature of the air in which it is placed, and in that respect possesses an advantage over glass.

Silica may be melted by exposure to a very high temperature. Before the oxyhydrogen blow-pipe, or in the flame of a spirit-lamp, fed with oxygen, it fuses to a clear bead. In the fused state it may be drawn out into long threads like glass. Fused silica dropped into water solidifies to a transparent mass, free from flaws, and remarkably hard and tough, so that it sustains the blow of a hammer without breaking, showing that it has become hardened, just as steel is hardened, by sudden cooling. It is very probable that this fused silica could be applied to many useful purposes if means were devised to prepare it in larger quantities. From its properties when fused before the oxyhydrogen blow-pipe, it is evident that, at a sufficiently high temperature, it could be worked like glass, and prepared in a variety of useful forms. To the chemist especially vessels of silica would be invaluable, as they would stand high temperatures as well as porcelain, whilst their power of conducting heat would doubtless prevent them from cracking so readily when exposed to sudden alterations of temperature. Another advantage of silica vessels would be that water and chemical solutions would have absolutely no action upon them, ordinary glass being very readily attacked by many chemical solutions.

PRINTING DIFFICULTIES.

BY A PHOTOGRAPHER'S ASSISTANT.

The time has arrived when with confidence I may venture to give publicity to the results of the experiments referred to in my last communication. Selecting for those experiments samples of highly albumenized paper, which, under ordinary treatment, yield a thickly studded crop of mealiness, I set to work systematically, determined to trace out the cause from whence originates the evil. Examining (with the aid of a powerful lens) the surface of a mealy print, produced on one of these papers, it at once occurred to me, that the irregularly mottled white spots, owed their existence to the removal of a portion of the slender film composed of reduced silver, which, previous to its exposure to the bleaching influence of the toning solution, had poured an unbroken coating over the entire surface of the paper. The thought suggested by this preliminary examination, at once enabled me to fathom the reasons, why highly albumenized surfaces, are at all times the most prone to the detested evil of mealiness. At this stage of the

enquiry I deemed it necessary to ascertain, as nearly as possible, the permeating power possessed by silver solutions of various degrees of strength, and to accomplish this I commenced with a bath containing 60 grains per ounce, then increasing its strength gradually with the removal of each piece of paper, I had, when finished, 6 pieces ready for exposure, whose surfaces contained silver in varied quantities, commencing with 60 grains, its minimum, up to 85 grains, its maximum, each having received the same amount of floating, viz.: 5 minutes.

The paper floated on the 60-grain bath when exposed to sunlight, yielded a print intensely red, the second that had been sensitized with a 70-grain solution, gave a tone slightly inclined to brown, the depth of this tone continued to increase with each remaining print, the shade varying in proportion to the strength of sensitizing medium. Cogitating upon the results thus produced, I at once arrived at the conclusion, that albumen in an undiluted condition, is capable of offering some considerable resistance to the efforts put forth by the nitrate of silver to unite itself with the chemically attractive chlorine, hence the reason why the first print was composed of little besides albuminate of silver, and that increased depth of tone was obtained from the graduated increase of silver, the additional strength enabling it to permeate the minute interstices of the film of albumen, and thus gain access to a more liberal supply of the chloride salts, and by a mixture of the violet hue, produced from the chloride of silver, with the red albuminate, the resulting colour assumed a purple or reddish brown—a colour, in fact, similar to a mixture of pigments—the above named tints when the proportion of red is the greatest. To convince myself that such was in reality the case, I went through the experiments a second time, giving the first paper half an hour's floating on the 60-grain bath, and the last, ten minutes exposure to the action of an 85-grain solution. When printed, the colour of each was as near alike as possible, viz. a reddish brown, but considerably deeper than was derived from the former trials; but still the red was in the ascendant, and an hour's floating on the strongest solution produced but little difference, which fact, to my mind, affords conclusive evidence that the silver penetrates a depth infinitesimally small when albumen undiluted is employed for coating to the surface of the paper. And here I would observe that paper albumenizers make a great mistake in the proportion of the chloride they mix with the albumen to be worked in its pure state. But more of this hereafter, as we have here to consider the conditions necessary to preserve the film of reduced silver uninjured during the toning operations. To do this, it is evident that gentle means must be adopted, or mealiness must assuredly follow; to effect this object I first pass the points carefully, but rapidly, through several waters, until all traces of liberated free nitrate ceases, they are then removed, a few at a time, into a flat porcelain dish, and thoroughly sponged (without this operation it is impossible to remove the whole of the free salt), after sponging and rinsing in a couple of additional waters, they are finally placed in a tepid bath, where they are left to soak half an hour, and then they undergo the toning operations: having ascertained the nature of the surface to be exposed to the toning solution, I, in my experiments, deemed it necessary to modify the bleaching power of the chlorine. An excess of soda would have accomplished this object, but at the expense of time and gold, I therefore had recourse to heat to produce a partial decomposition (thanks to Mr. Eliot for the idea). To the grain of gold I added $1\frac{1}{2}$ grain of carbonate of soda, which I find by experience is sufficient to start decomposing action, to this I added about half a pint of boiling water, then keeping the vessel near the fire for about ten minutes, carefully preventing the solution from reaching boiling point. This proceeding, with a continual agitating motion, tends to drive off the excess of chlorine, and the small portion of soda prevents the solution decomposing too far for toning purposes. This done the solution was laid aside to cool.

(To be continued.)

ON THE FORMATION OF THE PHOTOGRAPHIC IMAGE, &c.

BY M. OMMEGANCK.

THE constitution of the invisible photographic image has been the subject of numerous speculations and discussions, besides many important studies and researches, among which those of M. Testelin are of special interest. Without wishing to dispute the profound deductions of those who have devoted their attention to the investigation of this phenomenon, it may be permitted to me to offer some ideas, which, if not altogether novel, have certainly the advantage of solving the question in the simplest manner possible. It is indisputable, that wherever there is a modification of the material molecules, there is not only a change in the state of electrical equilibrium, but also a luminous and calorific modification; these three effects being like three chords of an instrument tuned in unison, one cannot be touched without putting the others in vibration. Nevertheless, we believe that a rational explanation of the phenomenon, under consideration, can be given by viewing the efficient causes from a more general point of view, instead of attributing them to an electrical influence, or to a kind of polarization produced by light.

The question is, What takes place at the moment the bromo-iodized collodion plate is exposed to the action of light? If the exposure be sufficient, the image is visible upon the plate in consequence of the decomposition of the salts of silver; the luminous vibration causes this decomposition, as heat reduces various salts of silver to the metallic state, and, to make use of a rough comparison, as the axe splits a log of wood. The luminous agent insinuates itself between the atoms of the iodine and the silver; but before the separation has become sufficient to disconnect them, there is a road to travel, a limit to pass, a dilatation to be produced, before the final rupture is effected.

There is also, what in chemistry is called, the "nascent state," being the peculiar condition of a body at the moment when it comes out of a combination, or forms a new one, a state in which it takes its natural course only after the lapse of a given time, and in which it subsists under a more dilated form. Is not a collodion plate, recently sensitized in the nitrate of silver bath, more impressionable at this moment than later, either when left in the bath or preserved in any other way? This is particularly appreciable in taking instantaneous pictures. We may, without difficulty, admit that the action of light brings the salts of silver to the extremest limits of the nascent state, before it effects their visible decomposition. If we pour the developing solution upon an exposed plate, the development, it seems to us, operates under the following conditions:—The developer, whether sulphate of iron or pyrogallic acid, decomposes the nitrate of silver with which it is mixed, this decomposition is moderated by the presence of a certain quantity of acetic or other acid. The decomposition would take place without the presence of a latent image. The molecules of nitrate of silver, before separating from their combination with oxygen and nitric acid, have a certain road to travel, and, consequently, a movement to perform; like an edifice about to tumble down, carries with it an arch about to give way, so does the decomposition of the nitrate cause the iodide to resume its natural state, and this last modification cannot take place without motion, accelerated locally and through a quasi-reciprocal action, by the successive decomposition of the nitrate. It is not the molecules of the nitrate already separated that we see floating in the developing solution, extracted from the nitrate and fixed upon a place, in quantities which go to form the image by an attraction more or less great in one place than in another: but the molecules of silver are proportionate to the light, more or less, which has acted upon the several portions of the plate.

(To be continued.)

ON PHOTOLITHOGRAPHY.

BY ANDREW MACTEAR.*

It affords me very great pleasure, indeed, to bring before your notice this evening, a system of photolithography as practised by Mr. Gibbons, in Glasgow, as far back as 1859, and to submit for your inspection some impressions by it, being the same which I showed to the old society a year ago, and which I am satisfied this meeting will pronounce to be genuine photolithographs, having all the appearance of the chalk-drawing mode. They are not shown as being perfect specimens, but as very creditable, and to show what might be done by its proper cultivation.

But before explaining Mr. Gibbons's mode, if you will allow me, I will give you a short history of the inventor and of the art of lithography itself, which gives employment to thousands, besides ranking as one of the most useful of the fine arts.

Germany, where type-printing was invented, and which has been the means of spreading the light of knowledge all over the world, also claims the invention of lithography.

Aloys Senefelder was born at Prague, in 1771, but soon after, he removed with his family to Munich. When he grew up he wished to be an actor, like his father, in Munich theatre; but his father was so much against it that he devoted himself to the study of jurisprudence, occasionally gratifying his histrionic appetite by performing in some of the smaller theatres, and employing his leisure hours in writing light dramas—one of which, he having been induced to publish it, realized him fifty florins clear profit.

At this time his father died, leaving a widow and family, and, being poor, he was unable to proceed with his academical studies.

The success of his first drama inspired him with such high hopes that he entered into theatricals, heart and soul, both as composer and performer, till, meeting with nothing but disappointment and misery for about two years, he gave up his profession as an actor to try his fortune as an author.

The next book he wrote turned out a failure, on account of the printer not having it ready for Leipzig fair; but it gave him occasion often to be in the printer's workshop, when an ardent desire possessed him to have a printing-press of his own, so that he could not only be author but likewise printer and publisher of his own works. He often afterwards said that, if his wish had then been gratified, he would never have been the inventor of lithography; but as this was not the case, he was obliged to have recourse to other projects. Amongst these was a sort of stereotyping—then etching with acids on different metals with various etching grounds, in which his knowledge of chemistry, gained at school, greatly assisted him. After trying a variety of etching grounds, viz., melted wax; turpentine and wax; turpentine, wax, and mastic, &c., with all their failures and disappointments, the one made with wax, soap, lac, and lampblack, which being soluble in water and easy to work with, was perfectly successful.

The repolishing of these metal plates, however, was so difficult and tiresome, that he was forced to give them up.

A slab of German stone, which he used for grinding his colours on, suggested the idea that it would not only be cheaper but easier to practise upon, a fine surface being both easily and quickly obtained, and they were so plentiful and cheap that they were commonly used for floors and pavements. He coated the surface of the stone with sulphuric acid, which formed gypsum, and then engraved his work, which he printed (same as with a metal plate) in the copperplate-press, but he never could get more than fifty impressions off, as the gypsum surface soon gave way, whereas, by his matured plan, and as now used, many thousands may be printed off by any careful printer.

* Read before the Glasgow Photographic Association, January 7th, 1863.

It was very fortunate that he found out the wax, soap, lac, and lampblack ground, as it opened up the way to chemical lithography. And now comes the interesting part.

A newly-polished stone was lying in his work-room, clean and ready to work upon, when his mother came in, and said to him:—"Aloys, please write down a list of the clothes for the washerwoman," who had then called, and was waiting for the "washing." He, having neither paper nor common ink at hand, wrote with his chemical ink on the clean stone, so that he might copy it at his leisure. Some time after this, just as he was going to wipe it off, the idea struck him—"What would be the effect of the writing, if I was to etch down the stone with acid, leaving the writing raised, and take impressions therefrom?" He at once set to work, and was fortunate in producing printed work from the stone for the first time; and thus was the new art invented. He now laboured hard to make himself master of this interesting art; but being unable to do so from want of means, he, for 200 florins, became substitute for a friend, as a private in the artillery of the Bavarian army, being confident that, with such means at his command, and devoting his leisure time to develop the art, he could soon be in a position to procure his discharge. But, alas! he was doomed to disappointment; for he no sooner arrived at Ingoldstadt with a party of recruits, than he was discovered to be a Bohemian, and, according to a recent order of the Elector of Bavaria, he was not allowed to join the army.

He left Ingoldstadt bordering on despair, and when he passed along the great bridge over the Danube he wished he had been drowned, instead of being twice saved from drowning when a boy, as misfortune persecuted him in every step he took.

He now resolved to serve as a printer; and he soon after produced some good specimens of music by his new art, which he showed to a publisher and to the court musician, and got an order for twelve songs—120 copies of each—which, being completed to their satisfaction, realised him a profit of seventy florins, when he thought himself as rich as Cræsus. A copy of this work having been shown to the Elector, he gave 100 florins as a present, to be divided between him and his publisher.

Being now possessed of means, he began to invent presses, one of which was a wooden frame on which was stretched a piece of strong cloth which he put on a table with hinges, the stone being fixed on the table, and charged with ink from a flat board covered with cloth (instead of the roller as now used); the paper was then put on, covered with a few sheets of damped paper, and the frame brought down like a tympan, when, after being well rubbed with polished wood or glass, the impression was made, and he was perfectly delighted at his success.

Again, however, disappointment attended nearly everything he did for about two years more, till, fortune being tired of annoying him, he, with an improved and most excellent press, and an order to print a prayer-book, made a brighter day dawn on the art.

As all was written backwards on the stone, he used to sketch it with a dark lead-pencil on paper, and reverse it on the stone by putting it through the press, when he was able to proceed to work with ease. Afterwards, instead of the dark pencil, he tried his chemical ink, and thus obtained a perfectly clear reverse. And now came the idea of using transfer paper with his chemical ink.

In the year 1796, after countless experiments, he was rewarded by the final attainment of his object; and money being now at his command, he matured the art, and produced work in every variety of style which is known and practised even at the present day, except photolithography.

In the year 1810, honour, money, gold medals, a pension from his Government, and an appointment as Inspector of Lithography, with a salary of 1500 florins a-year, permitted him to pass the remainder of his days in ease and comfort, when he not only painted some very creditable pictures, but

compiled his work on lithography, embodying all he knew with formulæ invaluable to his successors.

In issuing this work, he finished his introduction with these liberal words:—"God grant that it may soon spread all over the world; that it may prove useful to mankind, and contribute to their improvement; and that it may never be abused to any dishonourable or wicked purpose, and I shall then never cease to bless the hour in which I invented it."

In reading over the report of the first meeting of this session of the London Photographic Society in the *Journal of the Photographic Society*, when Mr. Osborne, from Anstralia, read a most interesting paper on photolithography—and which I think is the best mode for line work—it must have struck you, as it did myself, the rather unseemly way in which Mr. Poncey pounced on him, demanding an explanation of his mode of producing gradation of tint on the stone, and stating that nobody could do it like himself, which, nevertheless, he kept a profound secret. It reminds me of the little boy who, thinking himself very precocious, said to his father one day—"Papa, I can do what you canna do." "Aye," says the father, "and what's that?" "I can rin through between your legs, and you canna rin through between mine"—an idle boast, but comical withal. Mr. Osborne, in going through the subject, knocked the legs from Mr. Poncey by his "clearing-up" process, and proved M. Poitevin to be the real inventor of photolithography.

In working on the stone, either with the pen or hair pencil, a liquid ink is used, having a fatty substance as the principal ingredient; or if drawing with chalk on a grained stone, the chalk has also a fatty ingredient, which has been found to be the best medium to resist the wear and tear of printing thousands of impressions; and by transfers, with re-transfer ink, you may go on *ad infinitum*. The system of photolithography, therefore, approaching the nearest to this in principle will, I think, be found the simplest and best; and Mr. Gibbons's plan coming about the nearest to it, will be probably the soonest brought to perfection, if diligently practised, as it should be, when he freely gives it to the public at large, knowing that it is only "practice that makes perfection," and that it is impossible for him, alone situated as he is, to give it the attention it deserves, and that he would only be keeping back his portion of what is yet destined to play an important part in the art-world.

I will now submit Mr. Gibbons's system of photolithographing gradation of tints:—

1. Grain a lithographic stone with fine sand or emery-flour, taking care to avoid scratches; wash it well, and thoroughly dry it before using.

2.

SENSITIVE SOLUTION.

Copal varnish	1½ ounce
Raw linseed oil	½ "
Bi-chromate of potash	2½ ounces

Grind these three very finely, and put into a bottle; then add

Brunswick black	1 ounce
Mastic varnish	½ "
Turpentine	1 "

Put these three also into the bottle, and mix well together.

3. Coat the stone carefully with the above solution, by pouring a little on the stone, and roll over with a clean lithographic roller till it has evenly and thinly spread over its whole surface, which dries in a short time.

4. The glass negative is placed collodion side next the stone, and is kept from shifting by being stuck down by gummed paper round the edges. Exposure—from one to five hours, according to strength of light.

5. After exposure, remove the negative, and with a tuft of fine cotton-wool, soaked in linseed oil, rub gently over the stone, when the parts of the picture not acted on by the light will gradually come away, leaving the graduated tints quite firm. The proofs now shown were produced by this process.

6. The oil is now cleaned off the stone to prepare it for etching, which is done as follows:—Take a tall jug, nearly full of clean water, and place it in the hydrometer No. 1, when it will float at 0; then add dissolved gum-arabic, mixing it well till it floats at 6; then add nitric acid, mixing it intimately till it floats at 7, which is the strength found best for etching.

ANOTHER MANNER.

After the stone has been prepared as before, after exposure, it may be placed in a bath of turpentine or naphtha, keeping the stone in motion till the picture is developed.

ANOTHER,

By which very good pictures have been got.			
Brunswick black	1 ounce
Copal varnish	1½ "
Mastic "	1 "
Turpentine...	1 "

This is very much slower, the bi-chromate of potash being a very great accelerator.

7. With shoemakers' resin—or common pipeclay will do—make an embankment round the edges of the stone about one inch high (to prevent the solution running over the sides while etching); pour on the etching solution, and let it remain ten to fifteen minutes; wash off and charge with ink in the usual way, when the printing may be proceeded with. Care, however, must be taken that the stone is quite cold before doing so.

Mr. Gibbons has printed as many as between 2000 and 3000 from the one single positive, which completed a business order, and as many more could easily have been done, as the condition of the stone was perfectly good. He has always been fortunate, having scarcely ever failed while working in the country.

It is very interesting to examine the various steps by which photolithography has attained to its present position, which I will just glance at.

1. M. Nièpee, long before Talbot or Daguerre found out their processes, discovered the action of light on bitumen, and by it etched on steel plates. Then Nièpee de St. Victor used bitumen dissolved in essential oil of lavender, also for metal plates; and shortly after Mr. Macpherson, of Rome, adapts the same substance to the lithographic stone, and takes out a patent for photolithography by the "bitumen" mode.

2. In 1838-9, Mr. Mungo Ponton, of Edinburgh, observed and pointed out the peculiar action of light on bi-chromate of potash, which made it insoluble.

1853. Afterwards Talbot finds that it is the organic matter which is in combination with the bi-chromate of potash which becomes insoluble, and invents engravings by that process. Pretsch works on a similar idea, but makes a matrix from which he electrotypes his plates.

1855. Poitevin is the first to use the bi-chromate of potash for the lithographic stone.

1859. Asser, of Amsterdam, invents the transfer process. It may be remarked here that Sutton noticed that printers' ink, put on gelatine paper, would come away if soaked in water, leaving the paper quite clean.

Then Colonel Sir Henry James and his assistants improved upon Asser's mode, by passing through the press, on a stone charged with re-transfer ink, the exposed paper, instead of passing the ink roller over the wet paper, after the parts unaffected by the light have been washed away. Mr. Osborne hit upon a plan almost identical with Colonel James's simultaneously, being, at the same time, unaware of Asser's plan.

There are others deserving of great praise—Mr. Pouncy among the rest—for their ingenuity; but the names mentioned stand out in bold relief in connection with the different modes.

I may state here that the great retarding influence to photolithography is the dread of coming into collision with

"patent" rights; and I think it is a great pity to see such a grasping disposition shown by those who patent the various modes, especially as they are themselves so much indebted to those genuine liberal-minded men, who felt it a pleasure to give to the photographic world any knowledge they themselves possessed.

I may state that I became an experimenter after seeing Macpherson's pictures, which were exhibited in Glasgow at the meeting of the British Association, in 1856; but being afraid of patent rights, I gave it up, as the safest way of steering clear of those who intimated that proceedings would be commenced against any infringement.

It is now pretty generally believed that no patent is valid in this country. Should such be the case, and the various journals would give publicity to the fact, a great start and impetus would be given to it; and by all working diligently it would very soon occupy a very important place in the fine arts.

THE APPLICATION OF PHOTOGRAPHY TO THE MAGIC LANTERN EDUCATIONALLY CONSIDERED.

BY SAMUEL HIGHLEY, F.G.S., F.C.S., &c.*

It may seem strange (to some presumptuous) that anyone should wish a body like this Society to give an evening's consideration to that reminiscence of the nursery, the Galanty Show, to that toy of our boyhood, the Magic Lantern. Many scientific phenomena, when first discovered, either from their remarkability or beauty, have excited much interest in the popular mind, but have only been regarded by it as pleasing toys, till in the course of time their practical value has been discovered, and they have been ranked thereafter in the list of applied sciences.

Such was the globe of water, magnifying in distorted form the fly or flower, till in the hands of science it sprang into that exquisite refinement of optical knowledge, "the Microscope," that discoverer of hidden worlds and life, and the seat or form of disease within the inmost walls of the human frame. Such the Kaleidoscope, the tin case with its bits of coloured glass, regarded long only as a wonder from the fair, till in practical hands we find ourselves indebted to its aid for many of the beautiful geometric designs which ornament our walls or floors.

So, likewise, the Camera-obscura, the discovery of Baptista Porta, of Padua, till the progress of chemical knowledge revealed to us the means of fixing its fleeting images; and even then its products, together with its adjunct, the stereoscope, were little thought of in their most valuable practical bearings. Of late, however, this has rapidly impressed itself upon us, though we cannot as yet even see the limits of its educational utility.

In Microscopy, Natural History, Physiological, and Pathological research, what an invaluable agent does photography prove; for nature here depicts herself with her own pencil, and, possibly, ere long from her own palette, and in this resides one of its greatest values, for truthfulness is insured, and our studies are delineated with a faithful and unbiased hand; with what minuteness of detail the photographs I shall exhibit will bear witness.

I trust that I shall be able to prove this evening, to many who may not previously have given attention to the subject, that the magic lantern is likewise, with attention, destined to become an instrument of great educational value. We are most of us aware that natural history designs have been produced by the ordinary magic lantern colourist, and many such subjects, even when produced with care, have made us exclaim with Polonius that the representations have been—"very like a whale." Undoubtedly many subjects painted for the lantern are really artistic productions; but can the best artist for one moment pretend to cope with Dame Nature in her artistic moods? Can any artist (even if he be a pre-Raphaelite) for one moment hope to introduce the amount of detail she, with her undulating brushes of light, fixes upon the film, which her assistant the chemist, has prepared for her? For it must be borne in mind, that while the artist delights in broad effects, the naturalist regards detail

* Read before the London Photographic Society, January 6th, 1863.

as a *sine qua non*, their aims being different; and it must be patent to every one, that while the painted views we have long been accustomed to, meet every requirement, where mere amusement is concerned, photographic transparencies on glass will be the great means by which the magic lantern will be rendered subservient to the purposes of instruction.

Although many persons in private have employed photographs for the magic lantern, I believe that to Messrs. Negretti and Zambra the honour is due of having first produced for public sale subjects of geographical and artistic interest, specially prepared for the lantern; but I am not aware that any one besides myself has entered upon this branch of trade with special educational aims. I have long been impressed with the conviction that the lecturer on Botany, Zoology, Microscopy, Geology, Astronomy, and even on Pathology, would welcome as a boon truthful transcripts of nature that could be packed in a small space, and then shown on a scale to arrest attention in the student. This idea is actuated by no showman's feeling; for all persons who have had any experience in scientific educational matters know the value of appealing to the eye. Book knowledge, or that experience, gained even from the most graphic description, is of little value to the student who would become a true naturalist. He must see—if possible, handle—the objects of his study. The next best thing to this is to be familiar with the most accurate delineations of the forms he wishes to become acquainted with; and here photography offers her aid, and the magic lantern popularises her efforts.

But the naturalist is not the only favoured teacher; the art-professor may likewise avail himself of these aids to education, and so may the teacher of literature. In high-pressure steam days, like the present, the student has enough to do to make himself familiar with all that he is expected to be acquainted with; and if he really meets all the requirements of the Board of Education examiners, he ought to rank as the eighth wonder of the world. But, by the aid of Photography and the magic lantern (would that some more scientific, if not so familiar, a name for our instrument were recognised), teachers could kill two birds with one stone; for, while they were familiarising their pupils with the peculiarities of style of eminent artists, they might simultaneously convey to them the leading features in the works of celebrated authors such artists had illustrated. Thus I shall presently show on the screen how Kaulbach's wonderful style and Goethe's bitter satire may be illustrated by the photographic illustrations to "Reynard the Fox." Again, how Hogarth and morality may be combined, in the counterparts of the celebrated engravings of the "Good and Idle Apprentices;" and how the great stories of the Bible may be illustrated simultaneously with dissertations on the bold and vigorous designs of Schnorr. I will also show how the singing-master may avail himself our method, so as to place the words and music of a hymn, or other appropriate song, before a choir, when such subjects as Schnorr's Bible pictures are being exhibited in the dark.

And now to the means by which we accomplish our purpose. In the first place, the negatives may be those of the usual character; but, if taken expressly for the lantern, it should be borne in mind that the pictures should be included within circles. Whenever it is possible the negatives should be taken from nature, animate or inanimate; but there are many cases where this is impossible, and when a diagrammatic treatment of the subject is desirable. This specially holds good with many oceanic forms of life; for, when out of a sufficient bulk of their native element, they collapse, and look anything but "from the life."

Again, from the rarity of the subject desired, it may be necessary to resort to engravings; but no expense should be spared to procure them from the works of the best authorities, and in such a style of execution as is to be found in the works of Ray and Paleontographical Societies. If artistic, the negatives should always be taken from the originals, so that the characteristic touch of the artist may be ensured. Where negatives of microscopic objects have to be secured, we must adopt one of several arrangements that are founded on a common principle.

Negatives of microscopic objects may be produced by the method originally proposed by the late Mr. Joseph Delves, which simply consists of placing an ordinary microscope (from which the eye-piece has been removed) in connection with a solid or bellows-bodied camera, having a focussing range of from two to four feet, or a solar microscope arrangement,

fitted to the window of a darkened room, the room itself being used as a camera, as preferred by Mr. Wenham, or my own arrangement, which conduces to compactness of parts, and the optical portions being always in adjustment when required for use; or the arrangement of Dr. Maddox, who replaces the reflecting mirror with an Abraham's achromatised rectangular prism, and employs a Coddington lens for the condenser; or the arrangement of the Rev. W. T. Kingsley, who employs a very complex system of condensers, an achromatic eye-piece of peculiar form, the oxyhydrogen light, and determines the position of the chemical focus by means of a fluorescent screen. If low powers are to be employed, a microscopic plane mirror collects the light, and reflects it through the object-glass on to the sensitized collodion film, as shown in fig. 1. If, however, the higher powers are to

Fig. 1.

be used, it is sometimes preferable to collect the sun's rays by a long plane mirror, mounted with a rackwork rotating support, and adjusting screws, so that it can be made to follow the sun's course, and the light so collected is condensed on to the object either as parallel or convergent rays; in the latter instance by means of achromatic lenses having the same angular aperture as the microscopic object-glass in use, as in fig. 2. As, however, all microscopic object-glasses are "over

Fig. 2.

corrected," it is necessary to adopt some method for bringing the chemical image into focus on the film, after the visual focus has been determined on the greyed glass screen, and this is effected by aid of a micrometer head working on a screw attached to the stage (the parts being "kept up to their work" by means of a strong spring), the difference between the chemical and visual foci being determined experimentally for each object-glass for a given distance between the object and film; or, if great precision is desirable, special correction must be made for every object, for Dr. Maddox has found that the medium in which the object is mounted, its thickness, and the thickness of the cover, all have to be allowed for in securing perfection in the negative.

While, however, a considerable difference exists between the position of the chemical and visual foci in object glasses of low power, with the higher powers the difference is practically *nil*.

The great art in producing negatives of microscopic objects in the utmost perfection depends upon skill in the manipulation of the illuminating appliances, and I do not think anything has yet surpassed the photograph of *Navicula angulata*, produced in 1853 by the late Mr. Joseph Delves, a specimen of which (though, unfortunately, a faded one), is on the table. Negatives of microscopic objects may be produced by artificial sources of light, as the electric, oxy-hydrogen, camphine, naphthalised gas, or photogenic pyrotechnic mixtures, as recommended by Wenham, and employed on a large scale by Moule.

The International Exhibition.

REPORT OF THE JURY ON PHOTOGRAPHY AND PHOTOGRAPHIC APPARATUS.*

CARBON PROCESSES, PHOTOLITHOGRAPHY, PHOTOZINCOGRAPHY, &c.

In 1852 Mr. Fox Talbot patented the use of bichromate of potash and gelatine in connection with a process of photo-engraving. In 1855 M. Poitevin deposited, at the office of the Prefect of the Seine, a description of a process in which bichromate of potash and gelatine were combined with colouring matter for the production of photographic impressions. Since then a variety of processes, all of which have been modifications of the same idea, have been proposed and tried with greater or less success, and by means of some of which very beautiful results have been obtained.

It is needless to refer at length to the various other methods that have been proposed of producing permanent photographic impressions. The salts of iron, the salts of uranium, and other materials have been tried, but without that amount of success which would lead to their popular adoption. At the present time the salts of silver form the basis of all photographic processes commonly available; but the results obtained by some of the various carbon processes are such as to justify a hope that they may ere long take an established position in the production of photographic prints, and thus obtain a degree of permanency equal to that secured by any other method of pictorial representation.

Photo-engraving and Photolithography.—Amongst the most important methods of multiplying photographic impressions, are those in which an etched or engraved plate, or an impression upon the lithographic stone, are printed at the ordinary copperplate, typographic, or lithographic press.

The importance of these methods, as a question of economy, cannot be over-estimated; already a high degree of excellence is obtained, and there is every reason to hope for further improvements. In October, 1852, Mr. Fox Talbot patented a process for engraving photographic impressions on steel plates. This process is similar in principle to many which have followed. It consists in coating the steel plate with a preparation of bichromate of potash and gelatine; and the action of light upon this compound is to render it insoluble. A transparent positive picture being placed upon such a surface, the image is produced in insoluble gelatine, whilst the protected parts, consisting of the shadows, continue soluble in water; the plate after exposure, being washed, the soluble parts are removed, the insoluble remaining. The plate is then submitted to the action of an etching fluid, consisting of a solution of bichloride of platinum, which fills in the shadows, leaving the lights untouched. Mr. Talbot has, since his first publication, made many improvements in the process, the chief of which is a method of obtaining half tones by communicating to the plate a grain or aquatint ground, which is effected by dusting the plates with a coating of powdered resin previous to etching, and which is now done by perchloride of iron.

It will be seen that the principle upon which this process is based is capable of extensive application and modification: by a slight variation of the earlier details it is possible to obtain, not an engraved plate, but a mould or matrix, from which an image in relief can be produced capable of being printed at the ordinary typographic press. Considerable progress has been made both in this direction, and in photographic intaglio engraving, by Mr. Paul Presteh, who, by the judicious combination of photo-engraving and the electrolyte, has produced some results which are full of promise.

Other methods of engraving have been also suggested, one of which is based upon the principle by which the first permanent photographic impressions were ever obtained. The action of light renders insoluble certain bitumens. A plate of copper or steel, coated with such a substance, and exposed to light under a photographic image, is capable, after the parts not acted on have been dissolved away, of being etched by any corrosive fluid in the usual way. Other processes have been tried, but none have been hitherto brought to a higher state of perfection than that the principle of which has been described, and which, in the skilful and persevering hands of Mr. Paul Presteh, affords considerable promise that it may ere long be successfully used for book illustrations and similar purposes, with very slight aid from the engraver. The results are already very good, and in the reproduction of lines and points in any subject where the effect is not obtained by gradation of tints, the untouched image leaves very little to desire.

Not less important, and perhaps still more advanced to perfection, are the processes of photolithography, † and photozincography. The principle upon which the processes is based is analogous to that just referred to, but is entirely different in detail, and is so full of interest that a brief sketch of the operations is desirable.

In photozincography, Col. Sir Henry James proceeds thus:—A sheet of engraver's tracing paper is washed with a solution of bichromate of potash and gum, and exposed under a negative collodion to light; it is then passed through the press on a zinc plate charged with lithographic ink, the paper being perfectly and evenly covered. It is then turned over on a plate of glass, the back moistened with gum and water, which, passing through the paper, dissolves the gum and soluble portion of bichromate of potash to which the ink adheres, whilst the insoluble portion on which the lines and letters are unaffected. The hold of the ink to the blank part of the drawing having thus been destroyed, the paper is again passed through the press on a plate of zinc charged with ink. The second coat of ink brings away with it all that was on the blank parts, at the same time leaving a second charge of ink on the lines or letters. Some skill is requisite in all these operations. The transfer to zinc is made by the anastatic process, and so perfectly are the letters and lines charged with ink, that even four plates can sometimes be produced from one and the same photograph.

Mr. Osborne's plan is this:—A sheet of paper is prepared with albumen and passed through the press upon a polished plate of metal, then coated with a solution of bichromate of potash and gelatine, and again passed through the press. It is now exposed to the light, covered with the negative it is desired to copy; the paper is then passed through the press, face downwards, upon an inked lithographic stone, which gives the whole paper an even coat of ink, and the back of the paper is then placed upon boiling water, which coagulates the albumen; a subsequent short soaking swells the unaltered gelatine, and with it raises the corresponding ink from the surface, which a slight friction with a sponge removes. When the lines appear well defined, boiling water removes the last traces of the gelatine, and the print is dried. A lithographic drawing in greasy ink remains, which is transferred to the stone in the ordinary passage under the press. For the invention of this process, which Mr. Osborne has patented in Australia, the Government of the colony of Victoria awarded him £1,000.

Another process of photolithography now in use in the Imperial Printing Office, at Vienna, and used with much success, consists in taking a properly prepared collodion negative coated with gutta-percha, and removed from the glass in the way which was patented by Mr. Archer, in August, 1855. The polished surface of the stone is coated with one part of powdered asphaltum dissolved in thirty parts of chloroform; when dry, the negative is placed upon it and exposed for three hours in the sun, taking especial care that close contact is preserved; the negative is removed, and oil of turpentine, and, at the same time, water are quickly poured upon the stone; when dry it is ready to be handed to the lithographic printer, who first gums it in and then applies ink by the roller as if he intended to take impressions. When the stone is perfectly inked it is to be slightly etched, and again gummied, which completes the operation.

A variety of other modes have been proposed and practised with various degrees of success; but the most satisfactory processes are those described: although the production of half-tones yet remains to be accomplished, so far as the reproduction of lines is concerned, little now remains to be obtained. The saving effected to the country in Ordnance maps alone amounts to many thousands per annum. As another illustration of the economic value of photolithography, it may be mentioned that one of the Australian maps reproduced by Mr. Osborne, which formerly sold at two guineas a copy, has been reduced in price to three shillings. As a means of indisputably accurate reproduction of any document, either the same size, or on reduced or enlarged scale, it is impossible to overstate the value of the processes; for the copying of scarce and valuable literary works it is of the utmost importance: it has already been applied successfully to several such purposes.

DRY PROCESSES.

Leaving the methods of printing, or multiplying photographic impressions, and briefly recording the production of negatives, it is important to glance at what are termed the dry processes.

The wet collodion process having already superseded to a large extent all other methods, it soon began to be apparent that the necessity of taking into the field a dark tent, or portable laboratory, involved an amount of labour incompatible with the convenience of the amateur photographer. Attention was turned to the possibility of preparing the plate at home, and preserving the sensitiveness for use abroad.

The use of the dry albumen of Niepce de St. Victor did not become popular for a variety of reasons.

On the first introduction of collodion, in 1851, Mr. Archer, Dr. Diamond, and others had used the collodion plate, simply washed and dried, with some degree of advantage, but they were not enabled to secure satisfactory results. Messrs. Spiller and Crookes, in 1854, suggested the application, to the sensitive surface, of a solution of the nitrates of zinc, magnesia, &c., by which means it could be preserved for some time without injury, and kept ready for exposure.

The idea of using a neutral hygroscopic preparation for preserving intact the sensitive condition of the film, being once suggested, various other plans followed, and the use of glycerine, oxymel, and syrups of various kinds was proposed, each process, more or less satisfactory in the hands of those who advocated them. Mr. Shadholst and Mr. Maxwell Lyte, previous to Messrs. Spiller and Crookes's experiments, had used honey with much satisfaction in the results. These methods, as preservative processes, were attended by several inconveniences arising from the moisture of the preserved surface.

The process by which some of the best results have been produced, and which has grown, rather than declined, in popularity as time has advanced, is that known as the collodio-albumen process of Dr. Taupenot, which was published as early as September, 1855. This is an absolutely dry, and not merely a preservative process; it consists in applying to the excited and washed collodion film a coating of iodized albumen; this is then submitted to the action of a bath of aceto-nitrate of silver, washed, and dried. The plate is now ready for use; its chief drawback has arisen from its want of sensitiveness. Various modifications of recent date have, to some extent, removed this drawback: the process is practised with great success by some of the ablest devotees of the art.

The use of gelatine, metagelatin, malt, gum, and of a variety of other materials have also been proposed, and many of these substances, as coatings to the sensitive collodion film, are used by their promoters with success.

In 1853, Mr. Fothergill published, in the *Times*, a process based upon that of Taupenot, by which, not only were the manipulations much simplified, but additional sensitiveness was obtained. It consisted in applying to the excited and washed collodion film a coating of dilute albumen, which, having been allowed to remain a short time and permeate the pores of the collodion,

* Continued from p. 34.

† The following may be considered as a classification of photolithographic processes:—

On stone direct, using asphaltum as the sensitive surface on the stone—	
2. M.M. Lemercier, Lerebours, Barreswill, and Davanne, Paris	1853
3. Mr. Macpherson, Rome	1855
7. Printing Office, Vienna	1859
M. Nègre, Paris	—
On stone direct, using gelatinous substances with bichromate of potash on the stone—	
4. M. Poitevin, Paris	1855
6. Mr. Cutting, Boston, U. S.	1858
On Photographic "transfer paper," using gelatinous substances and gum with bichromate of potash on the paper—	
8. M. Asser, Amsterdam, gum and blotting-paper	1859
9. Mr. Osborne, Melbourne, who used gelatine and albumen	1859
10. Col. Sir Henry James, Southampton (Ordnance Survey)	1860
Other processes—	
1. M. Jobard, on stone and zinc direct, with the help of iodine, Brussels	—
11. Mr. Austen A. Turner, Boston	1860
5. M.M. Roussau and Masson, France, on stone direct with gelatine and bichromate of ammonia, &c.	1856
Dr. H. Hallcur, Bochum, on stone direct; two processes, one with oxalate of iron, the other with asphaltum	1854

was washed off, and the plate dried and kept ready for use. This process continues to be successfully practised by many photographers, especially for small plates.

Without referring to the many modifications from time to time proposed, the next important is the tannin process, discovered by Major Russell, which promises to be one of the most useful, simple, and popular methods of using dry collodion. It consists in the application of a solution of tannic acid to the sensitive film of collodion, which has been well washed, to remove any free nitrate of silver. The plate, when dried, is ready for use, and may be kept a very considerable time without deterioration. The simplicity of the operations, and the beauty of the results, are high recommendations to the adoption of this process. Some modifications have also been proposed with a view of increasing the sensitiveness of these plates, and from which, probably, more rapid results will be obtained. Dry collodion has, also, again been lately used with considerable success, simply by the addition of various resinous substances to the collodion employed.

The great desideratum, which, in dry processes, yet remains to be satisfactorily supplied, is an amount of sensitiveness equal to that of wet collodion. The use of hot development has been found an important auxiliary in this respect, which, with some other methods recently proposed, are now on their trial, and give great hope of success; but, with the exception of certain plates prepared by Dr Hill Norris by a secret process, the results of dry collodion continue inferior in sensitiveness to those of recent collodion.

(To be continued.)

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 21st January, 1863.

M. OMMEGANCK confirms M. l'Abbé Laborde's recommendation, on the score of economy and better results, of the introduction of a certain quantity of alcohol into the silver baths for paper positives. He employs the following solution:—

Alcohol	33 parts
Nitrate of silver	8 to 10	„

The result, he states, has greatly exceeded his expectations, as well as that of certain friends who have made the experiment. The paper is allowed to remain two or three minutes on the bath; it dries very quickly, prints more rapidly, the tones are infinitely superior, and are obtained with great facility.*

A series of clear fine days has caused our photographers to raise up from their winter apathy, and put their houses in order for the coming spring campaign. Public taste seems pretty equally divided between the miniature *carte de visite* portrait and the life size; photographers, however, do not appear at all ambitious to cultivate the latter phase of portraiture, so many difficulties attend its successful and profitable practice; and, as before, doubtless the *carte* will be the principal branch of the art carried on during the coming season.

There is not much left to say upon the miniature photographic portrait. With respect, however, to the *life size*, it may be remarked that herein lies a fine field for the artist's skill and taste, and, it may be added, profit also. A successful life-size photograph, enlarged from an instantaneous microscopic negative, possesses qualities which cannot fail to command the attention both of artists and the public. Those who are very exacting in demanding that a photographic portrait be truly correct as a likeness, insist that only instantaneous pictures can possibly fulfil that condition. The life-size portrait, when produced upon chloride of silver paper, owing to the length of the operation, requires the aid of a heliostat—a piece of apparatus necessarily costly, from its clock-work movement. Paper prepared with iodide of silver enables the operator to dispense with the heliostat; but perhaps the best medium of all for taking life-size portraits on, will be found in collodion on paper. The pictures are remarkably delicate in detail, of very fine tones, and unquestionably durable. A portrait life size may be obtained, even in dull weather, in five minutes, and with the simplest apparatus.

Those who prefer employing paper prepared with iodide of potassium for negatives, obtain it by imbuing the paper first with an alkaline iodide, and then floating it on a

nitrate of silver solution, or by reversing this order of preparation. This method may be modified by moistening the paper with a liquid holding iodide of silver in solution. We know of two solutions of this kind which, probably, might be advantageously employed on account of their sensitiveness. Both iodide of potassium and cyanide of potassium freely dissolve iodide of silver, forming a colourless liquid insensible to light, both of which, upon contact with nitrate of silver in excess, precipitate the iodide of silver dissolved, forming in the first instance a new portion of iodide of silver corresponding to the iodide of potassium in excess, and in the second instance cyanide of silver corresponding to the cyanide of potassium in excess. In these reactions the iodide of silver is precipitated under peculiar conditions, from whence results a much greater sensitiveness.

Photographers have a great prejudice against the access of iodide and cyanide of potassium during their operations; this prejudice is justified by the property these salts possess of paralysing the action of light wherever they exist in excess; but when the salt of silver predominates, all the conditions are changed, and there results only a formation of nitrate of potassa.

We do not know much about the sensitiveness of cyanide of silver to the action of light, and still less about that of the cyanide associated with iodide of silver in the nascent state. If the paper prepared according to the last process shows a great sensitiveness, we can perhaps apply this process to collodion, by adding to the iodide a minute quantity of cyanide of potassium, which, when pure, dissolves very readily.

In employing cyanide of potassium with paper or collodion, we may perhaps be obliged to fix with cyanide of potassium, if hyposulphite of soda be insufficient. This would be inconvenient and objectionable, because the cyanide rapidly dissolves the more delicate portions of the negatives; but if its sensitiveness be proved, it will be easy to find a less objectionable fixing agent.

We can also prepare sensitive papers, for enlarged portraits, by floating them on a nitrate of silver solution to which a small portion of gelatine has been added, thereby increasing the effect of the sizing.

To develop the picture, we must employ, instead of the acid sulphate of iron (which yields only grey tones of metallic silver), gallic or pyrogallie acid, with a small proportion of tannin, to fix the gelatine. We shall in this obtain very fine tones; and this silver bath, applied to a paper imbued with an extremely dilute solution of iodide of silver dissolved in iodide of potassium, will certainly combine all the conditions of a great sensitiveness, especially when in the moist state; leaving it, however, to dry partly, before developing, to prevent the gelatine from detaching itself, which it does, notwithstanding the tendency of the tannin and the reducing acids to fix the product.

From the infinitely small quantity of iodide of silver thus employed, these proofs might almost be fixed by simply washing them in water. They never fade, and if their hue be too red, they may be toned in the usual way by chloride of gold.

The great perfection of the mechanical and chemical elements of photography to which we have attained, and which every one desirous of practising the art can so readily acquire, leads to the conviction that the differences we now observe in the portraits taken by various operators are due to the good or ill lighting of the operating-room. The prevailing error I observe to be too much light, by which a flat, insipid picture results. In the supposed necessity for having an entire glass house to operate in, there is involved a great difficulty, and constant annoyance, in seeking to regulate the light, or get rid of the excess. There is plenty of room for the exercise of a little common sense in this direction, which would also lead to a great saving of expense in fitting up the studio.

* See letter on p. 30 on this subject.

THE PATENT ALBUMENIZED PAPER,

MY DEAR SIMPSON.—Your correspondent, Mr. Angelo Bianchi, writes as if it were a very easy matter to prepare my patent albumenized paper with the rubber solution, and he alludes vaguely to several persons who have employed this process.

To me it has had many difficulties, and the novelty of my patent consists in the mode of overcoming these practical difficulties, in great measure. All these novelties will be fully explained in my complete specification, if I complete my patent in the spring. In that case, your readers will know how I manage to succeed. But if all these things have been published before, and are generally known, there will be no necessity for me to tell people anything about them, and they can prepare their paper by M. Gaumé's, or anybody else's published formula, if they please, while I use my own process. If I am badgered about this patent, that is exactly what I shall do. My secret has not yet leaked out, and if I have to deal with many such gentlemen as Signor Bianchi it never will.

I send you a sheet of my rubber paper in which the albumen has entirely sunk in instead of lying upon the surface. You see there are many queer things which do not exactly lie upon the surface. Permit me to take this opportunity of publicly thanking you for the very kind manner in which you have reviewed my new work on the Collodion Process. I only wish it deserved half the good things you have said of it.—Yours faithfully,
THOS. SUTTON.

St. Brelade, Jersey, January 3rd, 1863.

[We have pleasure in inserting Mr. Sutton's letter, and take occasion to add one or two remarks on the subject. Whilst we shall have much pleasure in ventilating the subject fully, we would suggest that, until the complete specification of any patent is published, any question either as to its validity or efficiency is premature. And again, it should be borne in mind that the protection of any invention or discovery by patent is by no means necessarily a deprivation to the public, but often the contrary. If, for instance, a patented article be manufactured well and cheaply, the public are gainers by having the matter kept in good hands, instead of being at the mercy of many of those who, having no reputation in connection with the invention to lose, manufacture it with a view to profit rather than efficiency. Taking a patent is a more liberal course than maintaining a secret. The piece of paper enclosed forcibly illustrates the fact, that preparing paper with india-rubber and albumen is by no means all plain sailing. As we had before conjectured, Mr. Sutton intends permitting amateurs to use his patented process for their own prints with impunity. It is simply the commercial use he reserves to himself.—ED.]

TRANSMITTED POSITIVES, REVERSE ACTION OF LIGHT.

SIR.—The letter of your Paris correspondent in a recent number of the *News*, page 8, reminds me of a circumstance which happened to myself on one of the very fine afternoons we enjoyed last Autumn. I was exposing a trial plate (Fothergill), the subject rather a difficult one to bring out, being the front of my house—white, with a middling sized yew tree before it, two broad carriage drives coming to a point at the yew-tree, and a foreground of grass with dwarf bushes of laurustinus box and yew scattered over it—in raising the slide I incautiously allowed the back to be lifted about an inch, thus admitting a momentary flash of light to the interior of the camera, and by reflection thence, to the sensitive tablet; however, I went on, exposed the plate in the regular way, and took it back to the yellow room, where I developed a *positive by transmitted light*. The collodion was not very suitable for the Fothergill process, and the picture not a very good one, the sky being much marbled, but every spray of the dark evergreens is well made out, and so is the white house in the back-ground.

With the exception of the dash of light into the back of the camera, the manipulations and chemicals were the same as I generally make use of for negatives, and they have no novelty to photographers. I may mention, however, that the bath was slightly acid with acetic acid, and the developer was pyro and citric with a little nitrate of silver.

About six years back, when using the waxed paper process, I met with a somewhat analogous circumstance. A negative I was developing began to come out so foggy and bad that I took it from the bath and threw it into the open air. It caught my eye by accident two or three minutes afterwards, when, to my great surprise, it was developing into a positive so beautiful in half-tone, and other artistic qualities, that I have never seen anything in photography to equal it. I tried anxiously to fix it, but all the beauty disappeared in the hypo as rapidly as it had been developed. Very truly yours,—
RHO DELTA.

January, 6th, 1863.

Photographic Notes and Queries.

INSTANTANEOUS DRY PLATES.

SIR,—From the facts that are recorded from week to week in your Journal, it would seem that the problem of producing instantaneous dry plates will ere long be solved. I wish to suggest a probable method by which those plates may be produced, and some of your numerous readers may perhaps test its value before I shall be able to do so myself.

Mr. Keene and Mr. Frew have just published their plans of making tannin and honey, and tannin and gum plates still more sensitive, by leaving free nitrate in the film; theoretically, Mr. Frew's method seems the best, being less likely to produce unequal sensitiveness. Mr. Sutton's gum process is even more rapid than the above. Major Russell and others have also found the use of ammonia in the developer to lessen the required exposure.

I would therefore suggest that the plate be coated with Sutton's collodion, and excited in a bath containing no more acid than absolutely necessary, and thoroughly washed. Next, that it be coated with gum preservative newly made, to which $\frac{1}{2}$ drachm of a 30-grain solution of nitrate of silver and $\frac{1}{2}$ grain of citric acid has been added. Ammonia development at a moderately warm temperature would complete the process, which, from the facts I have cited above, should give rapid results.—Yours truly,
W. H. HARRISON.

Hivest, December 30th, 1862.

NEW MODE OF PIRACY.

SIR.—A species of piracy has lately made its appearance, which, if unchecked, is calculated to effect considerable injury to the numerous class of persons who gain their bread by the honest exercise of their professional abilities. I allude to parties extensively advertising for prints of cartes de visite, and other portraits, with a view to furnish the owners with a great number of copies at a reduced price. It is true that, with individuals who can appreciate and value a first-rate production, such a scheme will find but little favour; as a copy, however well it may be executed, can never be made to compare, satisfactorily, with a proof from the original negative. But the mischief arises from the fact that, to a great many persons requiring photographs, excellence of execution is of only secondary importance compared with the temptation of getting a great number for a little money.

I herewith send a vignetted "carte," which was furnished to a customer two or three months ago, for 3s. 6d.; future prints would have been 1s. each, or 12s. the dozen. I do not think this charge excessive for a good picture; and most persons, after taking a similar negative, would have reasonably expected to furnish 10s. or 15s. worth of prints from it. My customer, however, sent the print to a pirating establishment, got it copied, and received fifty proofs (such as they are), post free, for half a crown! the name of the copyist being substituted for my own on each of them.

Now, sir, I have no desire to comment on the moral attitude assumed by the respective parties to this transaction. To me it seems a simple act of robbery on the one hand, and of very great meanness on the other. But this is only my own

private opinion; and, as I fear I may be a considerable sufferer by such practices, I am anxious, if possible, to hit upon an efficient remedy.

The new Copyright Act enacts that any person executing a photograph, by order of another person, shall not be entitled to copyright therein, except an agreement in writing, expressly reserving such copyright, be signed by the parties at the time the work is executed. I, therefore, propose having a book, with a general form of agreement, written on the first page, followed by the signatures of parties for whom negatives are taken—non-compliance being the subject of an extra charge. I should thus be furnished with the legal means of punishing parties who infringe my copyright. I should be glad to know if you think this plan efficient and possible? I am pleased to find that unscrupulous copyists receive no mercy at your hands; and if you think the insertion of this note of sufficient interest to photographers at large, and likely to assist in exposing such practices, I have no objection to your publishing it.—I am, sir, your obedient servant,

FAIR PLAY.

Poole, January 17th, 1863.

[We apprehend that if sitters will consent to such an arrangement, and the pictures be registered, the plan will protect portraitists. The agreement should be so worded as to protect the public as well as the photographer, and secure sitters against the publication (without permission) of their portraits.—ED.]

To Correspondents.

* * Wanted, for full prices, or in exchange, the following numbers of the PHOTOGRAPHIC NEWS:—6, 9, 41, 49, 76, 80, 81, 91, 101, 104, 127, 197, 198, 200, 202, 203, 213, 214, 215, 216.

NOTICE.—With a good lens, and judicious manipulation, it would be possible to get a group of fifteen figures sufficiently sharp in a small negative to produce a good enlarged picture. 2. The precise details of composition printing vary in different hands. Each figure or group of two or three figures is taken on a separate negative, the general design and relation of each part to the whole having been determined beforehand. Each negative in succession is then printed on a sheet of sensitive paper sufficiently large for the whole picture, the whole of which is carefully covered from the light except the figure to be printed in, which in its turn is covered until all are finished. The mode of masking or covering up may be varied according to the ingenuity of each manipulator; the subject is too lengthy for detail in this column. Much depends on circumstances as to which plan would be best for a large group, a small negative of the whole enlarged, or a composition picture. The first would be probably the least trouble, the latter, in good hands, would probably give the best picture.

C. Upton.—Mr. Sutton's recent work is a very good one. The other works you name, especially the new edition of Bland's "Practical Photography," are very good.

F. L.—The advantage of a portrait lens over a view lens, as regards rapidity, arises from the fact that they may be used with a much larger aperture than the latter.

MR. G. S. PENNY offers a suggestion relating to alleged spirit-photography. He says:—"My request is that our cousins who operate on this particular class of subjects would send us for inspection a binocular picture of a material and spiritual pair. No polite spirit, so condescending as to submit to the scrutiny of one lens, would, I am sure, offer any objection to a sitting before a pair of lenses, provided no greater tax were made upon its time; and it would afford us valuable information as to its whereabouts, if not of its nature." Regarding Spenser's magnetic filters we cannot, unfortunately, give you information, as the subject has not come under our attention.

THOS. COLLINS.—We have more than once in different places called attention to the fact to which you refer, which is one well recognized by experienced portraitists both in photography and painting. In our own observation the nose slightly inclines in the majority of cases, to the right side. Thank you for the paragraph, which may be useful to many. We will make use of it. Thank you also for the suggestion regarding the YEAR BOOK. It is one we have more than once thought of; our chief ground of hesitation, hitherto, has been the desire not only to make it useful to all classes of photographers, but to keep it within their means.

J. R. IRATON.—It is not necessary to varnish glass transparencies, unless from slight over-exposure, or from over-development, or from something in the condition of the film, they seem to require it. If it be deemed necessary, any good varnish giving a glassy, textureless surface will do. The fine ground-glass for transparencies may be had of most of the dealers in photographic glass, such as Claudet and Houghton. Crystal varnish, with a little white wax added will answer the same purpose, as will also a little thin colourless starch.

AN AMATEUR.—Your negative is considerably under-exposed. In toning, the print should be immersed, not floated. If the bath be in proper condition ten minutes will generally be amply sufficient to tone a print; but in all cases the colour, rather than the time should be the guide. Always see that the print is sufficiently toned before removing it.

EXCELSIOR.—The addition of cyanide of potassium to a nitrate bath would simply cause a precipitate of cyanide of silver, which is insoluble, and after filtration no harm would be done beyond slightly weakening the bath. It has been recommended for purifying a bath, and is considered by some a valuable secret dodge. The cyanide of commerce is, however, so impure that it is difficult to say with certainty what the effect of adding it would be. In the case you describe, it is probable no great harm is done. Try the bath, and ascertain, if it work unsatisfactorily, sun it, and add a little nitric acid. 2. It is very easy to keep an iron solution for developing

positives a few months without much deterioration of its developing powers. Make the solution concentrated, 50 grains or more to the ounce, and add half as many minims of glacial acetic acid as there are grains of the iron salt. Keep it in a well-corked bottle, always inverting it, or placing it bottom upwards, so that the solution then flows round the cork, and less air is admitted than if the bottle were upright. The only change which will take place may be a slight amount of peroxidation, which will slightly weaken the developer, but will also, in our opinion, make it give a better positive. Dilute for use with once or twice its bulk of water, adding a drop of nitric acid for each ounce. Such a developer will give bright positives. Report on your glass in our next.

A CARLISLE SUBSCRIBER.—The best mode of rectifying the condition of a collodion which gives comets, is the addition of a little bromide. From a quarter of a grain to half a grain per ounce of collodion will generally make them disappear. If the defect arise from floating particles there is nothing but filtration, or settling. The collodion filter is said to be useful, but we have never tried it, always preferring subsidence for turbid collodion.

W. G.—Thank you for the cutting, we shall make a note of the case. We have not worked the morphine process, and cannot with certainty state the cause of the watered silk markings. Perhaps our correspondent Mr. Bartholomew can help you. In some other dry processes a similar defect is sometimes found; various suggestions as to its cause have been offered; but the most efficient remedy is, we believe, the use of an older collodion. 2. A single view lens of 6 inches focus, if worked with a large aperture, say half an inch, will, in a good light, and with first-class chemicals, in good order, give instantaneous pictures; but so far as we know, the particular lens you mention will not do it better than any ordinary good single lens.

ANGUS.—We are always obliged to any one, whether friend or enemy, who points out an error. The wish and attempt to do so without success, however, merely shows incompetency and spite. One or two of the statements were correct, and the result of a printer's error. Such, for instance, as P. for platinum, which should have been PL, as the opposite page shows. The other remarks present some curious blundering in the writer, but it is not worth while to answer them. Various authorities state equivalents differently. The list of inconsistencies and blunders in the similar table given in the other little publication you name are amusing enough; but we don't care to make reprisals. Besides, it would be breaking a fly on the wheel to criticise it. It is a compliment that ours is selected to examine for errors rather than the more abundant field at home.

W. G. H.—If you cement over the water-tight top a thin sheet of gutta-percha, or a piece of vegetable parchment, that is, parchmentised paper, it will prevent the sticking of the india-rubber.

W. WILSON.—There is no disadvantage, except the expense, in using any quantity of alcohol in the developer which does not precipitate the iron; neither is there any advantage in using more than is necessary to make the solution flow without causing greasy lines. 2. In introducing a ghostly figure into a photograph, let the figure enter for a few seconds at the close of the exposure, so that the figure may appear superposed upon the image already impressed, the first image being seen, as it were, through the last, giving it an unnatural or transparent effect.

J. H. UNDERWOOD.—We shall take an early opportunity of noticing your charming slides. We think it decidedly wise to publish them.

SIGILLI.—The plate sent had the appearance of having been left some time in a bath imperfectly saturated with iodide of silver, the film being consequently deprived of its iodide. The bath, however, smells very strong of ether, as if it had been much used. On trying a plate with a good sample of collodion in the bath, universal for was the result, indicating the presence of organic impurity. We added a solution of bicarbonate of soda, a little at a time, until there was a slight turbidity, which no longer dissolved on agitation. We then placed the bottle in the sun for an hour or two. The solution darkened very considerably, and threw down a black precipitate. The solution was now filtered into a bath, and a plate tried. The result was a clean, bright, good image. You may doubtless trace the remainder of your large bath in the same way with like success. 2. The collodion appears to be simply iodized, and has a tendency to give comets. The addition of a trace of bromide removed this. Adding a little of some bromo-iodized collodion will answer the same end.

J. ALEXANDER.—The stops of lenses are made black by a solution sold by chemists as "chemical bronze," which consists, we believe, of a solution of bichloride of platinum. The metal should be made quite clean and free from grease, and slightly warmed. The solution is then applied with a camel-hair brush. When dry apply a little blacklead with a brush. The tanning process, or the collodio-albumen process will probably answer your purpose best.

J. H.—You will find several articles in our last volume on the details of producing photographic transparencies. They are too lengthy to be given in this column. If you have not the volume we can refer you to the numbers.

JOHN SHELTON.—We fear the volume of "Photographic Proverbial Philosophy" will not be published.

E. C. LOCKE, D. M. A., CHARLES DERBY, SAMUEL FRY, and several other Correspondents in our next.

Photographs Registered During the Past Week.

By MR. GEORGE JAMES KEEL, 92, Renshaw Street, Liverpool.

1. Vignette Portrait of Rev. Robert William Forrest.
2. Ditto large half-length.
3. Ditto small half-length.

By MR. JOHN THORPE, 20, Grand Parade, St. Leonard's-on-Sea.
Carte de Visite of Roger Cooper Gardiner, Esq.

By MR. FRANK REYNOLDS, Churchtown, Dundrum, county Dublin.
Portrait of Garibaldi leaning on a spade, and surrounded by his goats.

By MR. EDWIN THOMAS HICKS, 45, Mackenzie Street, Everton, Liverpool.
Vignette Portrait of Barry Sullivan, as "Hamlet."

* * * THE Publisher desires to call the attention of photographers sending photographs for registration, to the instructions given in No. 225 (see p. 613). The photographer should himself fill up the form and sign it. It is also especially desired that care be used in writing proper names to secure legibility, as, otherwise, errors detrimental to the validity of a copyright may occur.

PRIVATE PHOTOGRAPHIC EXHIBITION AT NOTTINGHAM.

WE have received a large number of inquiries regarding an announcement which recently appeared in our advertising columns, and has been also widely circulated by means of circulars, referring to a projected photographic exhibition at Nottingham. Not a few of our correspondents suspect the scheme, others denounce it very freely, and some send for our private information particulars of a very damaging character.

When the matter first came under our attention, we must confess we viewed it with some degree of distrust. But, as it is *not* "our nature's plague to spy into abuses," we felt disposed to pass the matter by without further question or notice. The projector of the scheme, however, asks our opinion on the subject, and our consent to assist in adjudging prizes. We might have answered privately; the inquiries of many correspondents compel us, however, to adopt this method, and if we do not supply injurious information, we must at least offer an opinion. That opinion is in no sense favourable to the scheme proposed. In the first place, this is purely a private speculation. At the invitation of an unknown private individual, residing in a provincial town, photographers are requested to send him their productions for exhibition or sale. A "Contributors' Guide" is offered on receipt of six postage stamps. This, when received, consists of a circular of three octavo pages, containing the conditions of exhibition, one of which is very singular, and runs thus:—

"5. All articles intended to be competed for must be entered in the Secretary's book before the 1st of March, the charge being One Guinea, which shall be used for purchasing fifteen prizes, and procuring three impartial judges to be chosen by a majority of the contributors."

To say the least of it, such a system of raising the money for prizes, even if adopted by a responsible society, is vicious in the extreme. For the satisfaction of contributors it is announced:—

"3. That this exhibition will be protected by a joint stock company of five shares of twenty pounds each, to defray all expenses not covered by the charges on admission and *voluntary contribution*."

How the "joint stock company" is to protect the exhibition is not quite clear, neither is it clear whether such a company exists, or is yet to be formed. There are some other curiously worded conditions; but it is unnecessary to pursue the matter further. Neither do we intend to make use of the information forwarded to us bearing unsatisfactorily upon the projectors of the scheme. Whatever the respectability of the persons, the proposition is a blunder. Photographic exhibitions can rarely be successfully got up in provincial towns; but if the thing be a possibility at all, it can only become so in the hands of an active photographic society, of whom it is the legitimate province to manage such undertakings. When such a project is

attempted by private individuals, they lay themselves open to the suspicion of some kind of trade scheming for private purposes; and in this attempt the mode of procedure, and the conditions laid down, are such as cannot fail, we apprehend, to destroy confidence, and issue in entire failure.

ANOTHER TONING BATH WITH GOLD AND LIME.

M. JEANRENAUD proposes a modification of the toning bath. Considering that the process by *chloride of gold* and *acetate of soda* weakens the depth of the tones obtained by proper exposure, necessitating over-printing, he has sought a process free from these objections. He fills one bottle with

- A. Distilled water 9 ounces
- Chloride of gold 15 grains
- B. And another with distilled water 1000 grains
- Acetate of lime 10 grains.

The positives are printed strongly, then freely washed in rain water, and the toning bath is prepared in quantity proportionable to the number of proofs to be fixed. Thus for 2 or 3 proofs 12 by 10, take one ounce from bottle A and add to it two ounces from bottle B, and place the mixture in a porcelain dish, over a spirit lamp. When the liquid becomes heated it gives off faint nitrous fumes, which are immediately succeeded by a slightly acid vapour, arising from the acetic acid. The liquid soon becomes colourless, and commences to boil. A combination now takes place, and in this state the chloride of gold has no longer that corrosive action upon the proofs, which causes so many to be rejected. This operation is very rapid, as only very small quantities of liquid are made to boil at a time. The ebullition must not be prolonged beyond a few seconds, because the liquid, which becomes colourless just at the moment it comes to the boil, has then a tendency to become *yellow*, and thick, and in that state acts with less regularity, and may weaken the proofs.

The gold solution is now ready for use; it is only necessary to add sufficient distilled or rain water to immerse the proofs in, pressing them down below the surface with a glass triangle. It is best to keep a glass dish specially for the bath. The time required for toning depends upon the quality of the paper; a quarter of an hour suffices for French paper, half an hour for German; but with the latter the tones have much more strength and solidity. Lastly, to take every precaution against sulphurizing the proofs, before fixing them with a solution of hyposulphite of soda, strength 20 per cent., they may be passed through a bath containing a solution capable of neutralizing acids, such as water containing 6 or 7 per cent. of bicarbonate of soda.

This process is very economical, as with 15 grains of chloride of gold 25 to 30 half sheets may be toned. It is very convenient for amateurs, who, not having a large number of proofs at a time, require new baths frequently, and the consumption is in exact proportion to the work performed

as the solutions are kept separate until the moment they are required for use.

All the other acetates, such as those of strontian, barytes, and zinc, give nearly the same results; but the acetate of soda employed in this manner does not appear to combine with the chloride of gold, which it does not render colourless, at least when employed at 3 per cent., and it also acts very slowly.

THE PHOTOGRAPHIC EXHIBITION.

THIRD NOTICE.

WE have received numerous communications, from operators and others, regarding the opening of the exhibition in the evening, seconding our remarks, and urging us to press the subject on the attention of the authorities. We find those gentlemen upon whom the responsibility depends are most anxious to afford every facility, to every class, for visiting the exhibition, and profiting by the pictures exhibited. But opposing their desire to open in the evenings, they find the stern fact that, on former occasions, the cost has been greater than the receipts. As a means of meeting the difficulty, however, it is in contemplation to keep the exhibition open in the evenings during the last fortnight of the season. We cannot promise this as an absolute certainty, but believe that the authorities are so far desirous to meet the wishes of the photographers, that they will undertake this even at the risk of a little loss. Due announcement of the fact will be made.

We hope, before long, to be able to announce the decisions of the adjudicators in reference to the prizes to be awarded. The gentlemen who have undertaken this delicate task are pre-eminently well fitted for its satisfactory discharge. Mr. Joseph Durham, photographers know as a sculptor of eminence, a gentleman of highly cultivated taste in art, and a member of the council of the Photographic Society. Mr. Roger Fenton is known as a very able photographer, and one of the chief founders of the Photographic Society, and, having recently retired from the actual practice of photography, his decision must be free from the slightest suspicion of personal bias. In case of difference of opinion between these two gentlemen, they will elect an umpire to decide. The council have enlarged their intention, and six medals will be given instead of four, as was originally contemplated. These will be thus distributed:—

1. For the best portrait, or portraits.
2. For the best landscape, or landscapes.
3. For the best instantaneous picture, or pictures.
4. For the best contribution by an amateur.
5. For the best composition picture from life.
6. For the best reproduction or composition from still life, or copy of paintings in oil or water-colours.

In regard to several of the subjects there is sufficient distinctive superiority as to make the decision comparatively easy; regarding the landscapes, however, there are several so nearly balanced that the task of selection must be very difficult. We will not, however, anticipate the decisions.

Proceeding with the chief contributions in the order of the catalogue, we find a series of reproductions from paintings by Mr. M. H. Phillips. These are very excellent as reproductions, but the especial point which strikes us is the singularly photographic effect of some of the pictures. Here are two copies of pictures by MacCullum, "Autumn" and "Winter," either of which might very easily be mistaken for photographs from nature. The "Autumn" is a little dark and heavy, from the profusion of rich and warm colours in the original; but the "Winter" is an admirable picture, with a perfect *resemblance* which suggests forcibly the idea that the original was painted from photographic studies. Mr. G. R. Mainwaring has several frames of flowers and fruit, grouped with great taste, and exceedingly well photographed. These do not generally exceed the half-plate size, and are much more suitable for such subjects

than the large photographs of similar subjects exhibited by Mr. Fenton two years ago.

Still, amongst the finest landscapes are the contributions of Mr. Mudd. They are always well chosen and picturesque subjects, and, generally, at once brilliant, soft, and atmospheric. No. 29, the "Hermitage Bridge, Dunkeld," across the Braan, if we remember rightly, is a wonderful study of foliage, water, and large boulders. The thick masses of foliage are rendered with perfect detail, the water is transparent, and the large light-coloured stones in the foreground free from the slightest chalkiness. "Castle Crag, Cumberland" (No. 48), is another charming picture. Mr. J. H. Morgan has some very excellent landscapes. A couple of "Studies of Sheep," from life (Nos. 26 and 27), are very good, and giving just the head and bust, have a quaint and amusing effect. Mr. Mayland exhibits some fine landscapes of views in and about Cambridge, and some good interiors of difficult subjects, which have before been noticed in our columns. The Hon. W. Vernon exhibits some pretty good landscapes, but which do not, on the whole, justify that gentleman's reputation. Messrs. Fothergill and Branfill exhibit a number of pictures, from tannin plates, of scenes in Genoa. The majority of these have been exhibited before; they are clean and bright, wanting a little atmosphere, and sadly defaced with white-paper skies. "The Pieta," by Michael Angelo (No. 41), is a charming picture of a fine relief. Mr. C. Alfieri exhibits some good and some indifferent landscapes, those of "Furness Abbey" being best. Lady Jocelyn exhibits some views of Broadlands, Hants, which are delicate and detailed, but some of them a little wanting in atmosphere. One is a charmingly sunny thing, the fantastic shadows of foliage on a wall almost seem to flicker before the eyes. Mr. D. Combe exhibits a figure of a mounted volunteer, which is beautifully soft and round, but a little stiff and formal in the lines. Mr. Eidman exhibits a view of St. Martin's Church, from Pall Mall, intended to represent twilight. It is wanting in transparency, and looks dingy. Mr. Stephen Thompson exhibits a large number of landscapes, and some statuary. Amongst his contributions are many excellent pictures, of which we shall have to speak further, but many of them, especially those immediately before us, have the unfortunate fault in lighting, of which we have before spoken in this gentleman's productions, which gives them a flat and monotonous effect. "Kelso Abbey" (No. 31), "Tarsel Bridge, Flodden Field" (No. 40), and "At Richmond, Yorkshire" (No. 54), are notable examples of this characteristic.

Another little genre picture (No. 45), which, being unfortunately hung very high, is likely to escape attention, is well worthy of notice. It is entitled "A Happy Dream," and is by Messrs. Ross and Thompson. A pretty child lies sleeping, with happy peaceful countenance. A fairy-like female figure bends, or hovers about it, suggesting the idea of the "Angel's Whisper," as described in Lover's ballad. The general *ensemble* of the composition is good, and the transparent immaterial effect of the angel visitant is well managed. We commend this effect to the attention of Bullock Brothers, who made a great mistake not to call their "Footsteps of Angels" simply a fire-light effect, as which it would have won golden opinions. We regret that the hanging of "A Happy Dream" does not permit a more detailed examination.

We conclude for the present with a brief analysis of the processes represented in the exhibition. The number of contributions which are hung is larger than on any previous occasion, 825 frames being catalogued, whilst between one and two hundred have not found places. This shows an excess of contributions exhibited over the last exhibition of not less than two hundred frames. Wet collodion is now almost universally used, the proportion of other processes being less than ever. Upwards of seven hundred of the present contributions are by wet collodion; twenty-five by the collodio-albumen process, the chief of these being by Mr. Mudd; eighteen by the tannin process; eight by Dr. Hill

Norris's plates; twenty by the waxed paper process, all these being by French contributors; sixteen by various carbon and photolithographic processes; five by the Fothergill process; four by the tannin and malt process; two simply described as dry collodion; two by the honey process; two by the collodio-albumen and honey process; two by the metagelatin process; two by Corbin's collodionized paper process; one by the morphine dry process; one by the albumen process; and half a dozen daguerreotypes. The numbers of course refer to contributions or frames, which in many cases include several pictures. It is a somewhat singular fact, that whilst dry collodion processes have occupied so large a share of public attention, they are so meagerly represented here. In excellence, however, the dry processes present a more satisfactory result; some of the best pictures in the exhibition having been produced by the collodio-albumen and tannin processes, and their modifications. The Fothergill process puts in a very poor appearance this year; of the small number of contributions the majority being very poor indeed. The process has evidently been declining in popularity, and the results here exhibited will not be likely to give it a fresh impetus.

PRINTING DIFFICULTIES.

BY A PHOTOGRAPHER'S ASSISTANT.

THE advantages derived from the method described, for separating a portion of the chlorine from the gold, cannot be too highly estimated, as it gives us entire control over the bleaching power necessary to be exercised in toning operations; by the addition of soda in excess, the same results may be obtained; but, beyond a certain point, our controlling influence is lost, or at least uncertain in its operations. To those who have not made the science of chemistry their study, it may appear strange that the application of heat, whilst separating a portion of the chlorine, leaves the solution in a condition as acid as before, thus rendering necessary the same quantity of soda to produce an alkaline reaction; for the information of this class of inquirers, I shall endeavour to explain the reason why the separation of chlorine has no influence on the acid introduced with the gold into the toning solution. The chloride of gold usually sold for toning purposes, is made by dissolving a portion of the metal in a mixture of nitric with hydrochloric acids, or what is termed aqua regia: from the hydrochloric acid it derives its three equivalents of chlorine, so that, when separated by evaporation, it exists as a perchloride plus free acid in uncertain quantities; and this acid, which is a mixture of chlorine, hydrogen, nitrogen, and oxygen, we have reason to believe, separates itself from the chloride of gold immediately it is brought into contact with water; so that the heat, whilst exercising its decomposing influence upon the chlorine in combination with the gold, leaves unmolested the free acid, be its quantity great or small; consequently the same proportion of soda is required to produce alkalinity as would be required with the gold when in combination with its full amount of chlorine. Strictly speaking, the presence of soda with the perchloride is unneeded, whilst this last-named substance is undergoing the process of evaporation. But I am inclined to think that the presence of a small portion of soda hastens decomposition, not by its combination with the liberated chlorine, but by combining with the free acid it prevents the gold obtaining a fresh supply of chlorine from this source; so that, when a toning bath is to be used directly, it would, doubtless, be an advantage to add a larger quantity of soda than I have before named, the quantity being regulated by the amount of reduction required; but in no case where heat has been applied should the solution be strictly alkaline; for, except a trace of the stronger or the more faintly marked liberated carbonic acid be present, toning action will proceed but slowly indeed. It should ever be remembered, that the presence of an acid increases the bleaching power possessed by the toning

solutions, and here I would suggest, that this application of heat be resorted to for the purpose of giving the necessary qualities to the toning solutions hitherto considered unfit for use, until they have undergone a term of probation in penitential solitude upon some dusty shelf (not making use of those fanciful solutions, I merely give this hint on theoretical grounds).

Before proceeding with the details of my recent experiments, I would just observe, that I shall have occasion to offer remarks that may lay me open to the charge of inconsistency, they being somewhat at variance with the teachings contained in my letters recently published: but, be it remembered, I have been, and still am following, an almost unbeaten track; and, as I grope my way, I heed not the stones behind, though they for a time have supported my faltering steps, fixing my eyes steadily upon the goal of entire, undoubted knowledge of the subject, and throwing aside theories, useless as they are lumbering; after their work is accomplished, stepping from stone to stone, I move slowly forward, at the same time giving the photographic world the benefit of the faint gleams of light that have dawned upon my mind; and as the amount of light increases, I bring my increase of knowledge (if increase it be), and humbly add it to the stock of information contained in that best of photographers' hives, viz., the PHOTOGRAPHIC NEWS.

And now, without further remarks, I proceed to tone the prints described in the former portion of this paper: for, by this time, the solution is cold—or, at least, lukewarm—a condition most suitable for the present season of the year. Pouring this solution into the porcelain dish, for the sake of further tests, an addition of soda was made from time to time, commencing with half a grain, which, of course, left the solution still in an acid condition. The prints, which had been all printed the usual depth, viz., a full allowance made for reduction, I now commenced exposing to the action of the toning bath. No. 1, short floating, on sensitizing solution, became faint and slaty, with mealiness, though in a greatly modified form. No. 1, long floating, on ditto, retained a large portion of vigour, but still a faint trace of the same description of mealiness. The other prints followed in succession; those floating upon the strongest bath, though reduced rapidly, gave no trace of the disease until the slatiness began to appear. I now added another half a grain of soda to the bath. The reduction was not so rapid, but dark tones could not be obtained until mealiness in somewhat the same form made its appearance in the light background of the pictures; and now another half a grain was added—making in all three grains of carbonate (not bi-carbonate, remember) of soda to the grain of gold; the prints now toned more slowly, increasing rather than diminishing in vigour; those floated on the strong solution giving the most satisfactory results, although, for want of the strong bleaching power, all retained their over-printed appearance. This was just what I was in search of, a process that would give vigorous prints without any over-printing.

(To be continued.)

RESEARCHES IN HELIOCHROMY.

BY M. NIEPCE DE SAINT VICTOR.

FIFTH MEMOIR—CHAPTER .

On the Reproduction of Colours in Heliochromy.

I now state the results of the observations I have made during the past year, and, although the summer has not been favourable to my experiments with the camera obscura, still I have been able to obtain some proofs.

The obtaining of colours in the camera obscura best shows what heliochromy can give us; for here there can be no illusion, heliochromy cannot reproduce everything; but, nevertheless, it can give us many things; and thus it is

that I have the honour to present some proofs to the Academy, and, at the same time, of showing my mode of preparing the plates.

I have always found yellow the colour most difficult to obtain in the same space of time as the other tints; but I have recently discovered the means of developing the yellow with certainty, and of obtaining it in the same time as other colours. I had previously obtained, with great facility, red, green, and blue; but when yellow was produced, it was accidentally.

I have arrived at obtaining yellow in all my reproductions, by employing, as an agent for chloridizing my plates, a bath composed of hypochlorite of soda, in preference to the hypochlorite of potassa. This bath must be in the following conditions:—

Take a newly-prepared hypochlorite of soda, marking six degrees of the areometer; dilute it with one-half its bulk of water, and then add alcohol in quantity equal to $\frac{1}{2}$ per cent. of the soda, and heat the bath to a temperature of 180° to 190° F; then pour it into a flat capsule, half-plate size, stirring the liquid for a few seconds, immerse the plate in it at once, a time sufficient for the plate to take a black tint. It is then rinsed in abundance of water, and dried over a spirit-lamp.

In 200 grammes ($6\frac{1}{4}$ oz.) of this bath we can chloridize five or six quarter-plates, among which some will give better results than others, according to the thickness of the film and the degree to which the plate has been heated. In these conditions of chloridization the colours are produced (especially by contact) with very vivid tints, and, very frequently, the blacks appear in their full intensity.

To operate in the camera obscura, we select plates which, by the action of heat, have received a fine cherry-red tint, as well as those which are more slightly reheated, because they are the most sensitive to light. On this account the film of chloride of silver must not be too thick. But, to obtain the effects which I now describe, the chloridized plate must be covered with a varnish with a base of chloride of lead, as I pointed out in my last report, only we must take an aqueous solution of dextrine with chloride of lead, in order to neutralize the action of the alkaline bath upon the chloride of silver, and whiten the ground of the picture, which, without it, would remain rose colour, or dingy.

With regard to the problem of fixing the colours, I have only succeeded in doubling the time of duration announced in my last report. Many substances, added after the action of heat upon the chloride of lead, give a greater fixity than if the chloride of lead was alone; such are, among others, the tincture of benzoïn, chloride of tin, and aldehyde. But what has given me the best result is the tincture of Siamese benzoïn, applied to the plate while it is yet warm, and, after the plate has become dry, heating it until a little of the benzoïc acid is volatilized.

It is by means of this lead varnish that I have been enabled to preserve colours during three or four days, in an apartment strongly illuminated by daylight, in the month of July.

One observation I made is, that if we incline a heliochromic image, at a certain degree of incidence, the colours appear much more vivid, and the blacks assume the greatest intensity.

I have also remarked that, according to the manner in which the model (a doll) is illuminated by the solar rays, the obtaining the colours in the camera obscura becomes singularly modified, and produces very advantageous effects as to intensity of colour and brilliancy; as, for example, gold and silver lace, precious stones, &c.

But what is very extraordinary, is that, having placed a strip of unglazed black paper upon a large piece of silver lace, which the doll wore as a belt, the black of the paper was reproduced with the white of the silver lace.

Black is reproduced with a violet hue, viewed direct; but, if the plate be inclined at a certain angle, it assumes its greatest intensity, and the silver lace its metallic splendour.

Light, in changing the heliochromic colours made, in certain cases, changes green into blue, and yellow into green; as, for instance, if we cover them with a varnish having chloride of tin for a base, which, moreover, greatly retards the activity of the light; if it had not this objection, it would serve as a temporary fixing agent, for the reds are preserved a very long time.

CHAPTER II

On the Heliochromic Reproduction of the Binary Colours.

I HAVE now to speak of a series of experiments, which I consider very interesting in a scientific point of view.

I have proved that all the binary colours are decomposed by heliochromy.*

If the green be natural, like that of the emerald, arsenite of copper, oxide of chrome, sulphate of nickel, green carbonate of copper (malachite), they are reproduced green by heliochromy; but if the green be a compound, like that, for example, formed by a mixture of Prussian blue and chrome yellow, or that of stuffs, dyed by means of a blue colouring material and a yellow, or of certain glasses coloured by blue and yellow pigments, these greens, I repeat, give blue only by heliochromy, either by contact, or in the camera obscura.

I will mention another conclusive experiment: a light blue glass, superimposed upon a light green glass, give, by transparency, a very fine green; but, being applied to a heliochromic plate, they only produce blue; whatever be the time of exposure to the light, or whether the blue glass be uppermost or below, the results are the same.

Certain kinds of green glass reproduce green very well; others give only blue or yellow effects.

A yellow-green glass at first gives a light tint of blue, then a light green tint, and, finally, a fine yellow hue.

A green and a yellow glass, superimposed, produce a yellow upon the sensitive plate.

There are also other examples: a red glass, superimposed upon a yellow glass, giving an orange by transparency, produce only red upon the sensitive plate.†

A red glass, superimposed upon a blue glass, giving violet by transparency, first produce a violet (because the plate is naturally red); then blue follows: the red being replaced by an orange green, also quickly reproduces blue.

A white paper, coloured green, by green leaves, or by sap-green, is reproduced only very slowly by contact; the sensitive plate remains red a very long time, as if the light had no action; and if the exposure be prolonged, a bluish grey tint is produced; the same result takes place if we attempt to reproduce natural foliage in the camera, such as, for instance, the herbage of a green meadow; but if the foliage be a blue-green, as, for instance, the leaves of the dahlia, the blue tint will be more vivid. If the foliage be yellow or red, like that of dead leaves, the colour reproduced will be a yellow or a red, more or less pure, according to the greater or lesser absence of the blue matter, which, with the yellow, constitutes the green colour of leaves, as demonstrated by M. Fremy.‡

Lastly, it will be very interesting to reproduce Chinese green by heliochromy; we shall then discover whether it be a pure or a compound green.

The dye of a peacock's feather is well reproduced in the camera, that is, the colour appears under a certain degree of incidence, now green, now blue.

* As M. Edmund Becquerel has reproduced the solar spectrum complete, does this not prove that the colours of the spectrum are not decomposed by heliochromy? and is it not reasonable to conclude that these colours are simple, and that the solar spectrum is not formed, as Sir David Brewster asserts, by the superposition of three monochromatic spectra—red, yellow, and blue?

† I propose to repeat these experiments upon a plate not reheated, in order to ascertain if the red be still reproduced in preference to the yellow.

‡ In all the reproductions by the camera obscura, there is always a greater or lesser quantity of reflected white light, especially in the reproduction of foliage.

MEMORANDUM OF A PHOTOGRAPHIC TRIP IN NORWAY.

BY THE REV. ARTHUR COTTON, M.A.*

IN the early part of last summer I spent a few weeks in Norway, and, although the weather was most unfavourable for photography, an unusual occurrence, perhaps my photographic experiences may be acceptable to any brother in the art who is contemplating a similar ramble in this hitherto little photographed locality. The process I adopted was wet collodion developed with iron; the collodion, Thomas's, with bromo-iodiser, and the exposure with one of Dallmeyer's triplets, of which I cannot speak too highly, the exposure with the X stop varied from one second to a minute. The mode of intensifying was that with tincture of iodine, followed by pyrogallic acid, and this, by painting on an edge of varnish to the negative, I was always able to carry out, without risk of the film splitting, after the picture was fixed and dried, thereby reducing the quantity of water, a matter sometimes of importance, and the list of chemicals required in the field.

The ordinary mode of travelling in Norway affords great facilities for working the wet process, but I regret I had not also with me a few dry plates. Boats and carriages are the railroads of the country, men and horses are provided by law for fixed stages, at a very cheap rate, so that the cost of posting from ordinary stations does not exceed twopence an English mile.

The carriage, as most people are aware, is not an omnibus, being constructed only to carry one, and affords little room for luggage. It has no springs, consequently photographic traps have to be carefully packed, and craftily arranged.

Behind the body is a board about twelve inches wide, and two feet six inches long, and my tent, which was one of Rouch's, and contained camera, chemicals, &c., for the day, was swung by means of stout straps underneath this, thereby diminishing the jar upon its contents. On the board my portmanteau was strapped, but nothing that could not bear jolting could be carried in it. As a proof of this, I might mention, that the screws of a fishing reel packed in it were jolted loose, and a box of flies were pounded up so completely as to leave little else but hooks and the fluff of feathers.

Between my feet, in the body of the carriage, was my store box of chemicals, glasses, &c., and here they were fairly protected, the spring of the shafts taking off the jolt, but only a small box can be carried in this position, as even a little weight here is felt by the horse, and becomes serious as he gallops, as a Norwegian horse does down the almost perpendicular hills which abound. Moreover, the width of this part of the body, which is shaped somewhat like a canoe, is inconsiderable, and provides no room for one's feet, which rest outside against a cross-bar, which extends from one shaft to the other.

The camera stands, fishing rods, &c., were strapped to the shafts.

By promise of additional drikke-penge, or drink-money, a mere trifle, to the boy who sits on the top of the portmanteau, I was able to stop on any part of the stage; but I seldom availed myself of this, in consequence of the almost incessant rain.

The straps which secured my tent to the carriage board also served as its knapsack support, when, as was sometimes the case, I took a man on foot over the hills, who was well satisfied with two marks a day, amounting to 1s. 8d., and went up hill with his load as easily as I could without one.

Having said so much as to the arrangement of my impedimenta, which are always serious matters to a photographer, I would only recommend future travellers to take unusual precautions to preserve their negatives by very careful pack-

ing. I was not provided with grooved boxes, having always safely carried my varnished plates with blotting paper between them; and some of my best pictures were ruined by the rubbing they were exposed to in the carriage.

I have only a few hints to give, as far as my experience goes, as to the most interesting parts of the country in a photographic point of view.

Bergen is about the centre of an extremely beautiful country. North and south of this town, and within a day's steam, is the best of that scenery for which Norway is famous.

First, there are fiords 50 or 60 miles in length running up to the very backbone of the country, which in Norway is a mountain chain at no great distance from the coast, and out of these fiords the mountains rise almost perpendicularly several thousand feet.

No. 26 is a poor specimen of this feature of the country taken during a heavy rain on a very gloomy day. There are waterfalls, of which No. 18 is an example, 900 feet in height, but dwarfed in the photograph, from the impossibility of getting such a view as to give an idea of distance.

There are churches of the quaintest style of architecture, if they are of any style at all. Of these I have two or three specimens. No. 30 is a view of a noble river, the Rauma. No. 21, a view of one of the farms which, up the country, supply the place of inns, and provide good accommodation for man and beast.

With ordinary weather, I should have taken a great number of (to me) most interesting pictures, but ill-health during part of my stay in the country, and bad luck in the weather obliged me to leave a great deal of work for a future opportunity, nor should I, had it not been for the request of my friend Mr. King, have ventured to lay before you the accompanying selections from my negatives, or thought of troubling you with these few observations.

ON THE ACTION OF NITRATE OF SILVER UPON ALBUMEN.

BY MM. DAVANNE AND GIRARD.

THE employment of albumen as an additional sizing for positive paper, in connection with the action it exercises upon nitrate of silver, and the modification which may result in the proofs, is a subject that very properly engages the attention of the photographer.

We have been much gratified at seeing that the researches made subsequent to those which we presented to the French Photographic Society, in December, 1859, have confirmed what we then said upon this subject. The Abbé Pujol has recently called the attention of photographers to the combination which takes place between albumen and nitrate of silver, a combination but little studied hitherto, but upon which we have made some experiments. M. Roussin has lately shown that this combination alone, and well washed, is sensitive to light; and that with it we have even been able to obtain positives on paper. He has also obtained negatives upon glass developed with gallic acid. Mr. Spiller has also confirmed this fact, which we had stated, that albumenized papers also retain silver in the parts unexposed to light, even after fixing and the most careful washing. We should doubtless have preferred that these authors had known and mentioned our previous researches; but, as we have referred to them, we need not enter upon further details.

The combination of albumen with nitrate of silver varies according to the strength of the silver bath. Thus, in treating 5 drachms of albumen with 5 drachms of nitrate of silver, we obtained very different precipitates, according as these 5 drachms of silver were dissolved so as to form solutions of 15, 10, 5, 2½, or 1 per cent. With the solutions of 10 and 15 per cent., the albumen is strongly coagulated; it gives a heavy, abundant precipitate, which may be collected on the filter in the form of distinctly separate pellicles.

* Read by Mr. W. W. King, at the North London Photographic Association, January 21st.

With weak solutions of silver, the quantity of the precipitate is much less considerable. A notable quantity of albumen remains in the bath in a state of solution. The portion precipitated is soft, gelatinous, and sticky. A rapid analysis seems to prove that the compound of albumen and nitrate of silver is much poorer in albumen when it has been formed in presence of a more dilute solution of silver, which readily explains, by this cause alone, that the albumen, less strongly coagulated, is carried off by the washings.

In view of these facts, we can easily understand that a weak silver bath allows a portion of the albumen to be dissolved without coagulating; it thus becomes charged with organic matters which alter it; and the proof, much less rich in the argento-organic compound, does not acquire that brilliancy and vigour of tone which is due principally to this compound.

This combination of albumen and nitrate of silver is analogous to that which it forms with bichloride of mercury. It is insoluble in water, and sensitive to light even after perfect washing. When the light is intense, the compound rapidly assumes a red colour, and soon bronzes; but a feeble diffused light produces no perceptible colour; and this explains why papers strongly albumenized, and which are not chlorodized in proportion, yield, under the same negative, and by the same light, proofs in which the contrasts are harsh, and the details in the shadows less distinct. Under the influence of light, therefore, a decomposition takes place, nitric acid is separated, while a portion of the albumen remains combined with the silver. This latter combination is insoluble in hyposulphite of soda, and the total of these facts gives us the theory of the formation of positive or negative albumenized proofs, even in the absence of every other salt of silver; but it remains to be explained why the best reserved whites of the positive proofs, after fixing and washing, still retain silver if these proofs have been taken upon albumenized paper, while they retain none if taken on paper simply salted.

Some experiments enable us to explain this anomaly. We have found that the quantities of silver thus retained upon white sheets of paper, and well fixed, vary in considerable proportion.

Whatever care may be taken even by fixing the compound of albumen and silver immediately after sensitizing, we have always found a certain quantity of silver which the fixing agent has not removed, and which is probably owing to the formation of a little sulphide of silver. Albumen is, in fact, a sulphurized body, which most frequently, in contact with hyposulphite of soda, disengages a very strong odour. The quantity of silver which thus passes to the state of sulphide is very inconsiderable. It is this which imparts to the whites of our proofs a light tone which perhaps can only be appreciated when these whites are in direct contact with the margins. But there are other circumstances which cause the quantities of silver retained in the albumenized papers to vary; these are the preservation of the paper and the action of diffused light.

For while a whole sheet sensitized and immediately fixed gave, upon analysis, only a quantity of silver equal to 0.010, that which had been prepared the day before, fixed under the same conditions, gave 0.020.

Lastly, another sensitized sheet, dried, and exposed for a few moments to diffused light, although it did not become discoloured, contained, after fixing, 0.016 of silver. The experiment, several times repeated, has always given, with some variations in the proportions, analogous results.

We have therefore to conclude:—

1. That always, when albumen is in presence of nitrate of silver, it forms a small quantity of a compound insoluble in hyposulphite of soda (probably a sulphide).

2. The time that elapses between the sensitizing of the paper and the fixing with hyposulphite of soda, increases the quantity of non-fixable silver.

3. Diffused light acts in an identical manner, even when it is too feeble to colour the proof.

Now we know that a good negative must not have absolute blacks; the light can then always influence the largest whites of the photographic proofs, all the parts of which must necessarily contain silver.

But we do not think that the presence of this minimum quantity of silver can have the least influence upon the keeping of these proofs; and we all know that a great many proofs have existed a good number of years and have not undergone any appreciable change.

In connection with this practical question, the proof of the persistence with which the silver remains allied to the albumen throws some theoretical light on the subject.

We now understand that albumenized negatives may, up to a certain point, be developed without the addition of nitrate of silver, because the albumen has energetically retained a certain quantity, while non-albumenized and well washed negatives can be made to appear only after the addition of the necessary quantity of nitrate of silver.

And, as diffused light causes a portion of this compound of silver and albumen to pass to the insoluble state in the hyposulphite of soda, we can easily explain what appears abnormal in the experiments of Mr. Young, where the proof was first fixed in the dark in hyposulphite of soda; then, after proper washing, developed in full light by gallic acid *cum* nitrate of silver.

This experiment succeeds only with albumen negatives, and after a good exposure. The preceding facts give a very simple explanation, as in these circumstances an argentic-albumen compound is produced, which the hyposulphite of soda does not remove, and upon which the developing agents cannot act.—*Bulletin de la Société Française de Photographie.*

A SHORT LESSON IN PHOTOGRAPHY.—No. 8.*

THE melainotype, after development and fixing, *may* appear far from satisfactory; the whole surface appears dim, indistinct, and covered as it were with a veil; there seems to be a metallic film, a thin and semi-transparent film, pervading the surface of the picture; in fact, we have a specimen of what is technically called a "foggy picture." This is not an uncommon phenomenon with a new bath—one newly prepared, and it is very likely to occur with every new bath if the nitrate of silver used in its preparation be genuine and neutral. With an old bath the evil in question is known to every photographer; there is, perhaps, not one who has not had the misfortune to complain that his pictures were fogged, that his bath was out of order, and that customers had to be sent away until the calamity in the bath had been rectified. Whenever this fogginess manifests itself, however, we fortunately know its remedy. The bath in such a case is either *alkaline* or *neutral*; the remedy is: to make it *slightly acid*. This remedy can be effected in three ways: either by adding a drop—sometimes even only half a drop—of acid to the bath, by adding tincture of iodine to the collodion, or to the bath. The result of my experience teaches me to make it an imperative duty never to *doctor* the bath, that is, never to introduce any extraneous chemicals, but those which enter unavoidably through the collodion. To filter the bath frequently is a benefit; to boil it in a glass retort or a matras is a benefit; for, by the first operation, it is freed from innumerable fine particles of undissolved salts of iodine, which are found in every bath after it has been used awhile; and, by the latter process, the alcohol and ether, that have been accumulated from the collodionized plates, are distilled off, and the solution of nitrate of silver is thereby concentrated—but *add neither acid nor alkali*. I admit that the addition of acid will correct fogginess, that acid is a sure remedy in most cases; but my belief is that the bath is thereby deteriorated, and will soon approach its end: that is, that a

* From *Humphrey's Journal*.

new bath will soon have to be substituted in its stead; but what is to be done? cry nearly all the photographers in a breath. The answer from a few scientific operators and from myself is: "Doctor your collodion."

Whenever fogginess presents itself on the surface of your collodion, add tincture of iodine to the collodion until it assumes a wine colour; now try a picture: an improvement will assuredly be the result; if the picture be not yet quite clear, add a few drops more of the tincture, until all fogginess has disappeared. By observing this plan, each collodion surface is *doctored*; for it carries upon it that which produces a liberation of nitric acid by chemical decomposition, and this liberation takes place at the right time, on the right place, and in the right quantity.

Tincture of iodine for photographic purposes is prepared by dissolving iodine in the *strongest* alcohol; you must be very careful not to use an inferior article of alcohol, because the water which it contains would injure the collodion by coagulating the pyroxyline.

The evil of fogginess having been corrected and remedied, let us now proceed and wash the picture after it has been properly developed and fixed. Inasmuch as we have two fixing solutions, namely—*hyposulphite of soda* and *cyanide of potassium*, it might be a pertinent question to know which is preferable for the melainotype. Photographers give a preference altogether to the latter solution; and why? Because of two properties: in the first place it acts quicker on the unsolarized iodides; secondly, it is a reducing agent, and acts as such on the silver film, producing a beautiful silvery white appearance in the high lights; in the negative this silvery whiteness is not required, and is thought by some to be injurious; so that hyposulphite of soda is considered the proper fixing solution by many distinguished operators for negative pictures.

After the melainotype is thoroughly washed from all traces of cyanide of potassium, it is dried, generally by the artificial heat from a spirit lamp (alcohol lamp). In this operation you must exercise great care lest you raise blisters on the japanned surface of the picture; for an undue heat on any point will, with several specimens of the iron plate, produce almost inevitably the evils alluded to. A small light properly managed, so that the heat is well diffused over the whole surface, by moving the posterior part of the plate gently over the flame, backwards and forwards, will dry the collodion surface without disrupting the japan from the iron.

As soon as the operation of drying is finished, the picture is ready to pass into the hands of an artist, in order to receive the touch of his magic pencil. Various little particles on the background, in the drapery and elsewhere, will soon disappear as he proceeds with his artistic improvement; parts, before gray and indefinite in character, assume shades distinct and agreeable; besides this, he works in a slight shade of colour on the cheeks, which communicates a life-like brilliancy to the picture, which before it did not possess; in fact, it gives a roundness to the features which before were flat and deathlike. Even the drapery itself may, at this stage, receive its natural tinting if desired; good taste, however, eschews much colour; a vulgar taste seeks the gratification of strong contrasts, and hence of high colours; for such a taste you will have to *gild* buttons, ear-rings, breast-pins, and watch-chains; for such you will have to *paste* on colour to obscure every other shade beneath; and for such, unfortunately, the artistic photographer has frequently to cast his pearls before swine; his bread, however, is the gain; and it is the part of a *business man*, at least, to sacrifice all preconceived notions to the desires of his customers.

When all colouring, gilding, and tenebriating of the hair with lamp-black are finished, the picture is flowed with the proper varnish, in the same way as the plate is flowed with collodion. The varnished surface may then be gently dried by the side of a small light artificially, or allowed to dry naturally by rearing the plate on the end, from which

the varnish flowed, in the corner of a pane of glass in the window.

The picture, after this operation, is ready for mounting in a case, or simply in a mat for transportation in a letter by the mail.

THE COPYRIGHT OF PHOTOGRAPHS.

CHARLES DANIELS a photographer, carrying on business at No. 1, Penton-place, Pentonville, was charged before Mr. Barker, at Clerkenwell, on Wednesday week, with selling a copy or colourable imitation of a photograph of Mr. Sothorn as Lord Dundreary, without the consent of Henry Hering, photographic artist, of 137, Regent-street, the proprietor of the subsisting copyright of such photograph, and knowing the said copy or imitation had been unlawfully made.

Mr. Brandt, barrister, instructed by Mr. Bowen May, of Russell-square, attended for the complainants; and Mr. Pook, solicitor, of Basinghall-street, for the defendant.

The defendant pleaded "Not Guilty."

Mr. Brandt, in opening the case, said that he was instructed by Mr. Bowen May in his capacity of solicitor for the protection of the photographic trade, and not in connection with the trade or profession of engravers. Mr. Hering had published portraits of Mr. Sothorn in ten different positions in his character of Lord Dundreary, and as soon as those portraits came out they met with an enormous sale. Shortly afterwards the piracies complained of appeared in windows in different parts of the town for sale at a much reduced price; and an inquiry being set on foot, two of the spurious portraits had been purchased at the shop of Messrs. Palmer and Sutton, in Tottenham-court-road; and that firm, on being applied to, gave the name of Mr. Daniels, the present defendant, as the person from whom they received the supply. On this information being given by Messrs. Palmer and Sutton, a letter was written to the defendant by Mr. Bowen May, in the following terms:—

67, Russell-square, Dec. 31, 1862.

"Sir,—I am instructed by Mr. Hering to take proceedings against you to recover compensation in damages for selling pirated copies of his photograph of Lord Dundreary. If you at once come forward, give up the name of the manufacturer—if you are not he—and undertake not to offend again, my client will be satisfied with the payment of a very small penalty. Your immediate attention is necessary."

Of this communication the defendant did not take the least notice. After an inspection had been made of the photographs at Palmer and Sutton's, Mr. Bowen May wrote the following letter, dated January 2, 1863:—

"I have satisfied myself that you did sell to Messrs. Palmer and Sutton the pirated photographs; and, unless you forthwith give up the name of the manufacturer, I must assume you are unable to do so, from the fact that you have the negatives and print yourself."

Still no reply was received, and hence the present summons was issued under the 6th section of the 26th and 27th Victoria, cap. 68, entitled "An Act for amending the laws relating to the copyright in works of art, and for the suppressing the commission of fraud in the production and sale of such works." The complainant having some doubts as to whether his productions might be pirated, had published on the face and back of them that they were copyright, and therefore the defendant could not plead ignorance of the fact.

Mr. Henry Hering, the complainant, was sworn and deposed that he had published many photographic likenesses. Among others he had published portraits of Mr. Sothorn in the character of "Lord Dundreary," in ten attitudes or positions. Two of the portraits now produced were his, and on them he had printed his name, with the words "Copyright secured," and on the back his address, "H. Hering, photographer, 137, Regent-street." These photographs he had registered in the proper manner at Stationers' Hall, and the certificates of registry he now produced. He would swear that the photographs now produced (the imitations) were "positives" obtained from "negatives" of his production, and which were included in the certificate of registration. He had never given any consent or authority to the defendant or any other person to copy or publish copies of the portrait or any other.

In his cross-examination by Mr. Pook, the witness stated that he had first obtained the consent of Mr. Sothorn to sit for his portrait at the latter end of July last, and the registration

was not effected until the 30th of August. He denied that he had sold any of the portraits until after the registration had been completed. He had not obtained any written, but merely a verbal permission from Mr. Sothorn to publish the portraits. There was not a single copy sold until several days after the portrait was registered; and of that he was certain; and after the permission was obtained he went on printing them and keeping them in stock until the registration was perfected.

By Mr. Brandt.—I would not even let Mrs. Sothorn have a copy until it was registered. (Loud laughter.)

Mr. George Bishop was next called, and proved that he was a member of the firm of Marion and Co., 23, Soho Square, who were wholesale agents for Mr. Hering, the complainant, and other photographers, and that he purchased the photograph produced (the pirated copy) at the shop of Messrs. Palmer and Sutton, in Tottenham-court-road, on the 29th December last. He paid 6d. each for the copies.

Joseph Kershaw, aged 17, deposed that he was an assistant in the service of Messrs. Palmer and Sutton, and that he remembered selling to the last witness the photograph (the piracy) now produced. The photograph was purchased by his employers from the defendant, Mr. Daniels, among others which were brought to his masters' establishment by the defendant's boy.

The witness was severely cross-examined by Mr. Pook, with a view to show that he could not swear to the identical portrait he had sold to Mr. Bishop being part and parcel of the lot supplied to his employers by the defendant, Mr. Daniels. He only knew it was purchased by the firm to which he belonged, by the fact that he saw the goods paid for by a lady in the shop. The first lot consisted of ten dozen, and the second of five dozen. The money was paid in his presence. Of the portraits thus supplied he could not swear that the identical portrait now produced formed part of either parcel. Of this he was sure—that all the portraits of Mr. Sothorn, as Lord Dundreary, which his master had in stock, came from the defendant in the parcels he had mentioned.

Mr. Bowen May was next called, and proved that he was the attorney for the complainant in this case, and that the letters which had been read had been written by him to the defendant. On a subsequent day the defendant had called upon him. On being shown the portrait in question, as well as one of Sir E. Bulwer Lytton (both of which had been purchased at Messrs. Palmer and Sutton's), he said that the former had been published by him. The latter he denied all knowledge of.

Mr. John James, clerk to Mr. Bowen May, corroborated this evidence.

Mr. Brandt then informed the Court that Mr. Mayall and other eminent photographers were present, who could prove that the imitative portrait must have been taken from the original of the complainant.

Mr. Pook, for the defendant, said it had not been proved that the defendant had any knowledge that a copyright had been registered, or that he had any notice that a copyright existed. The same question had been raised elsewhere in the case of "Gambart v. Powell," in which Mr. Corrie, the magistrate, had dismissed the summons.

Mr. Brandt.—That was a summons issued under the provisions of another Act of Parliament—viz., the 17th of George III., and had nothing whatever to do with the statute now under consideration.

Mr. Pook resumed, and said, though that might be so, there had since been a decision in the Court of Common Pleas in which Mr. Justice Willes had given judgment against a photographer in a similar case, and in that instance a motion for a new trial, moved for by Mr. Coleridge, was now pending. He took two points on behalf of his client, the defendant, and the first was that there had been no proof of any agreement in writing by Mr. Sothorn for the publication of his portrait; and secondly, that if any such agreement had existed, and the copyright had been registered, it had not been brought to the knowledge of the defendant, as was contemplated by the Act of Parliament under which this action had been brought.

Mr. Barker said he was quite satisfied with the evidence before him that the defendant had been guilty of the wrongful act imputed to him under the summons and proved in evidence; and in order to give him, if he would be so advised, an opportunity of appealing against his (Mr. Barker's) decision, he should remit the penalty to the sum of £3 0s. 6d., with power of appeal, and award £2 2s. for costs.

The defendant next pleaded "Not Guilty" to a summons issued at the instance of Mr. John Edwin Mayall, photographer,

of Regent Street, for the pirating and publishing of a photograph of Sir E. Bulwer Lytton, M.P.

Mr. Mayall deposed that Sir E. Bulwer Lytton had sat to him for his portrait at the latter end of July last. He registered the portrait on the 21st of August, and of that registration he now produced a certificate. The three copies or imitations now produced were piracies of that copyright. There had been an attempt to alter the incidents of the picture by an alteration of the curtain in the background, the table at which the figure stood, and the carpet, but these were changes which any photographer with a pencil and colour could accomplish; still he was convinced that the portrait was a piracy of his original photograph. The copies were a disgrace to any man pretending to a knowledge of photography.

In his cross-examination by Mr. Pook, the witness said he had the written permission of Sir E. Bulwer Lytton to publish the portrait in question, but he did not even allow the honourable baronet himself to have a copy until he had registered it.

Evidence was then given as in the previous case.

Mr. Barker said that this case was as clearly proved as the former one, and his decision must be the same—namely, £3 0s. 6d., with the same power of appeal, and £2 2s. costs.

At a subsequent sitting, Mr. Barker was informed that Mr. Pook, the solicitor for Mr. Daniels, who was convicted at this court, on Wednesday last, for selling copies of photographs of Mr. Sothorn as Lord Dundreary, and of Sir Edward Bulwer Lytton, Bart., M.P., had withdrawn the appeals he had given notice of, and that the cases were at an end, as the fines had been paid into court. Mr. May had been asked to accept of a mitigated penalty; but he now could not do so, as he had, on behalf of his clients, and before any expense had been incurred, explained to Daniels that he had rendered himself liable to heavy damages for printing the above portraits, and offered to accept a few shillings' penalty, merely to impress the fact on Daniels' memory. This liberal offer had been refused, and further expenses had been incurred by notice of appeal having been given. The money which had been paid into court, amounting to £10 5s., would hardly pay the expenses that had been incurred; and, under the circumstances, Mr. May could not think of asking the magistrate now to mitigate the penalty. From what had come to the knowledge of Mr. May, there could be no doubt that the money did not wholly come out of the pocket of Daniels, but was found by an association.

Mr. Barker said that he should only have inflicted a nominal fine had not the defendant asked that such an amount should be fixed as to enable him to appeal. As he had not gone on with the appeal, and as the money had been paid into court, he should at once give an order for the amount to be handed over to Mr. May's clerk.

Proceedings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting was held in Myddelton Hall, Islington, on the evening of January 21st. Mr. W. Hislop in the chair.

The minutes of a preceding meeting having been read and confirmed, the following gentlemen were elected members of the Society: Messrs. P. E. Coffey, E. G. Wood, J. R. Thompson, T. R. Williams, J. Martin, and Mr. Snoad.

A number of new stereoscopic slides, instantaneous and otherwise, by Mr. Wilson, of Aberdeen, were exhibited by Mr. G. Wharton Simpson; and the three reproductions by Mr. Annan, distributed this year to the Glasgow Art Union, were exhibited by Mr. Dallmeyer.

Mr. W. W. King then proceeded to read a paper entitled "A Photographic Trip in Norway," by the Rev. Arthur Cotton (see p. 53). A number of very interesting views, taken with Dallmeyer's No. 8 triple, were exhibited as illustrating the paper. One of the best photographs and most pleasing pictures was stated to have been taken between 8 and 9 o'clock at night. After some conversation about the pictures, a vote of thanks to Mr. King was passed.

Some conversation on Mr. Annan's reproductions, which were much admired, followed.

Mr. SHADBOLT produced some prints which were exhibited as specimens of toning, regarding which a manufacturer of albumenized paper wished to obtain an opinion as to which

was best for portraiture and which for landscape, as a guide to him in preparing the paper. As no information as to the method of producing the respective tones was forthcoming, no expression of opinion as to their value was elicited.

Mr. DAWSON, referring to the specimens of Mr. Wilson's stereographs before the meeting, said they were very beautiful, as all his pictures were; but many of them displayed a great amount of curvature in the lines, showing they had been taken with a single lens. This was a serious defect in architectural work, and it was somewhat strange that such a lens should be used for such a purpose, seeing that others were now to be obtained.

Mr. HILL said that Mr. Wilson did use other lenses, as many of the pictures he had in the Exhibition were with the triple lens.

Mr. DAWSON was referring to the pictures now before them.

Mr. DALLMEYER remarked that Mr. Wilson had been using a single lens, which he had recently made for him, for instantaneous stereoscopic work; its peculiarity being, that it might be worked with a very large aperture. In the ordinary stereoscope, with a lens of six inches focus, in which these views were intended to be inspected, the slight curvature of lines would be corrected, as it had a tendency to produce the opposite kind of distortion to that exhibited in these pictures, and thus, in the stereoscope, the lines would appear straight. As for views not intended for the stereoscope, the time had come when photographers would not tolerate views with curved lines; and, for larger pictures, Mr. Wilson used the triple achromatic lens; and he had just been making him a camera with swing back, which, permitting the plane of delineation and the object always to be parallel, prevented convergence of the lines when it was necessary to tilt the camera. The triple lens then gave absolute freedom from distortion in architecture; and, for landscape purposes, he thought he only need to refer to some of the pictures of Col. Stuart Wortley to show how pre-eminently fitted it is for giving brilliant results in that kind of work. For stereoscopic interiors he thought a double combination was best, and he might refer, as examples, to the stereoscopic pictures of the interior of the International Exhibition, by the Stereoscopic Company, which were taken with his No. 1 B.

Mr. DAWSON, referred to a recent visit he had made to Mr. Wilson, when he saw his various lenses, and some very beautiful pictures. Some of his lenses only cost a few shillings.

After some further conversation, in which the tones of the prints exhibited by Mr. Shadbolt were again canvassed, he said he believed the difference in tone was due simply to the different proportion of chloride and albumen used, the same salt being used in all. In some there was a slight pink tint in the whites.

Mr. SEELEY thought that no rule could be laid down for uniformity of tone. The sentiment of the subject should be considered, and the kind of negative. A soft negative required the most brilliant white paper, whilst a hard one was sometimes improved by a little degradation of the whites.

Mr. SYDNEY SMYTH exhibited some instantaneous stereographs, taken at Plymouth, which were much admired. In answer to questions, he explained that they were produced with collodion made by himself, containing two grains of bromide to each ounce, and equal portions, of iodide of cadmium and ammonium. The lens was one of Shepherd's card portrait lenses, of 6½ inches focus, with a stop of about ⅙ of an inch.

Mr. DAWSON said the difference between these pictures and Mr. Wilson's, consisted in the fact, that, whilst Mr. Smyth's had manifestly been taken with an enormous flood of light poured through a portrait lens, Mr. Wilson's were taken with a single lens and small aperture. He took care to have his chemicals in such sensitive condition, that he got the instantaneous effects with these appliances that others got with large aperture and portrait lenses, and thus the general definition, and especially the distances, in his were superior.

Mr. SEELEY asked if it were not generally understood, that a single lens with small aperture was equal to a compound lens with large aperture, owing to the number of reflecting surfaces in the latter, all decreasing light.

Mr. DALLMEYER said something was undoubtedly lost by the number of reflecting surfaces, but much less than was often represented or fancied. The proportion of loss calculated by Professor Petzval for central pencils was only one-thirtieth part of the whole. It was not possible to use a single so as to work as quick as a double combination. Knowing that the single lens gave greater depth of focus than the portrait com-

bination, he had taken the new single lens he had made for Mr. Wilson to Mr. Williams to try. They tested it with the No. 1 B, using with the latter a stop of 1¼ inch, and with the other a stop of ⅙ inch. The result was that the single lens gave a bare positive, whilst in the same time the double lens gave an over-exposed negative. Perhaps it might be well to remember that in the majority of Mr. Wilson's subjects a quasi-instantaneous exposure was admissible, and where perfect instantaneousity was imperative the double combination should be used. Mr. Breese, who used his new stereo compound lens of 3½ inches back focus, or 4¼ inches equivalent focus, told him that he was able to take the moon quite instantaneously with it. Now Mr. De la Rue has always found it necessary to give at least five seconds, and it followed from the difficulty of following the moon's course that much less perfect results could be obtained by a prolonged than an instantaneous exposure.

After some further conversation, the proceedings terminated.

The International Exhibition.

REPORT OF THE JURY ON PHOTOGRAPHY AND PHOTOGRAPHIC APPARATUS,*

THE APPLICATIONS OF PHOTOGRAPHY.

THE applications of photography are already such as mark a high destiny for the art, and are a source of proud gratification to those who have been associated with its history and progress.

In portraiture, its most widely-extended and popular application, its value, in contributing to individual and social happiness, by placing within reach of the lowliest, as well as the highest, the treasured mementos of absent friends, scarcely needs affirming. The extent to which the class of portraits known as *cartes de visite* have been circulated, is almost beyond belief.

Its aid and connection with various sciences, as a faithful recorder, has of late years received ample recognition and illustration. In the magnetic and meteorological department of the Royal Observatory at Greenwich, photography is in daily use, and proves of inestimable value as a registrar of the magnetic and atmospheric variations. To the invention of Mr. C. Brooke, F.R.S., and the subsequent adaptation of the late Mr. Welch, the public are indebted for many useful applications of photography to the registration of natural phenomena. Under the able superintendence of Mr. Glaisher, every perturbation of the magnet during each of the twenty-four hours is self-registered by the aid of photography. The thermometer and barometer are made, by its aid, to record their own variations. Similar registrations in different parts of the world afford facilities for accurate comparison, and contributions of the utmost importance are thus secured towards the systemizing, and establishing, upon certain data, meteorological science.

The contributions of photography to pictorial art have been many and important during the last ten years. Perhaps the most interesting of these have been in the department of instantaneous photography, by which the evanescent and changing aspects of nature are seized and rendered permanent ere they have had time to change. Those fleeting and ever-charming atmospheric effects which, "ere a man can say, behold the jaws of darkness swallow," or which are—

"Just like a snow-flake on the river,
A moment bright, then gone for ever,"

are depicted with the rapidity of light—preserved for future contemplation.

The advancement in the chemical branches of the art; the improvement in optical appliances, and the increased skill in manipulation, have enabled photographers to secure various phases of the ocean in calm and storm, and under all conditions of light and sky, and atmospheric effect. Crowded thoroughfares filled with rapidly-moving figures and vehicles are accurately rendered, the uplifted foot caught and depicted in mid-air, never to fall.

Vesuvius in eruption, with its rolling volumes of smoke, is caught and fixed upon the tablet of the photographer. Apart from the pleasure obtained from the examination of such pictures for their own sake, their value to the painter, in reducing his labour and increasing the truthfulness of his results, is of very great importance.

The small images, which are usually obtained by instantaneous processes, are, moreover, capable of amplification by such appliances as the solar camera, and other means which have been recently brought to a high state of perfection. Photography itself has also aimed at emulating the productions of the painter, as well as aiding him by supplying him with studies; and the composition groups of Rejlander, Robison, and others, give much hope of successful results in this direction.

The production of natural colours by means of photography remains to be accomplished; but the labours of MM. Becquerel and Niepce de St. Victor afford hope that such an end is not beyond the range of possibility. Within the last year, the latter gentleman has succeeded, not only in producing colours, as in an original, but in preserving them for a few hours. The fact, once accomplished, establishes the possibility, and the means only require to be defined and verified.

A record of the progress of photography, as illustrated by all its applications, would far more than fill the space allotted in this Report. Suffice it to say, that there is scarcely a branch of art, of science, of economics, or, indeed, of human interest in its widest amplification, in which the applications of this art have not been made useful.

In addition to those applications of which we have spoken, it may be briefly added, that photography has, by the rapidity and uncompromising truth of its delineations, aided the psychologist in his studies of the physiognomy of mental disease or abnormal emotion, as the portraits which have been publicly exhibited strikingly illustrate.

It has aided the study of medical science by its truthful representation in

* Continued from p. 46.

morbid anatomy of malformation and disease generally, and by its record of the progress of cases and illustrations of surgical treatment.

As an aid to ethnological science, no mode of delineation can compare with it. Its unerring truthfulness has been found of unsurpassed value to the student of every branch of natural history, as is shown in the productions of Comte de Montizon, and others.

In giving a permanent form to the enlarged images of the microscope, it has added a truth and value to the productions of the micrographer which could not otherwise possess.

The archaeologist and antiquary, the virtuoso and historian, have gladly acknowledged its value, and sought its aid. With the architect and engineer it supersees, and far surpasses in many cases the drawings made by hand. For them it records unerringly the progress of works from which the directing mind may be thousands of miles distant.

It enters the court of justice, and becomes the unchallengeable reproducer of documents; or, pursuing the criminal, it silently, but indisputably, identifies him in a land where he is unknown.

For the manufacturer it depicts his designs, patterns, or workmanship with facility and truth not to be equalled, illustrations of which are to be found in every part of the present display of the world's industry.

And lastly, more ambitious still, as if the globe were too narrow a sphere for its resources, it travels into space, seeking and taking records of the phases of other worlds, and of that great body the sun, to whose subtle and "archchick" gift it owes its power and life.

It is satisfactory also to know that the status of photography is still further recognized by an Act of Parliament, passed last session, securing copyright in photographs, hitherto not given by law.

(To be continued.)

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 28th January, 1863.

You will remember that the Academy of Sciences proposed last year, as the subject of competition for the Bordin prize, the following important photographic question:—

To determine by experiment the causes capable of influencing the differences of position between the optical and the photogenic foci.

Several elaborate *Mémoires* have been addressed to the Academy, two of which obtained prizes. From M. Fizeau's Report I extract the following passages.

"A short time after the announcement of the discovery of Niepce and Daguerre, when so many persons ardently devoted themselves to the production of pictures drawn by light, observers attentive to giving the greatest possible sharpness to the images soon remarked a singular fact, viz.: that the pictures obtained were not generally satisfactory, when the plate was placed exactly in the optical focus of the lens, that is to say, in the plane where the eye perceived the image of an object with the greatest distinctness, while the proofs presented a much superior sharpness when the plate was placed at a certain distance from this optical focus, in a distinct place which has been designated the *chemical* or *photogenic* focus."

Experience has shown that the difference of position of these two foci may be observed with the various sensitive films employed at the present day in photography, but that it is generally very variable, according to the quality of the objective, and also with the size of the images obtained by means of the same objective. In certain instances the state of the atmosphere also exercises a marked influence which, however, is but slightly apparent in ordinary circumstances, and may be overlooked.

The first *Mémoire* we now report upon bears the device, "Theory is the Explanation of Facts by Real Causes."

The author commences by establishing the fundamental fact of the difference of position between the optical and chemical foci by means of experiments, the specimens of which accompanying the *Mémoire* add to the clearness of the demonstration. The fact being well established, the author, in seeking the cause, analyses with much sagacity the complex circumstances which result from the achromatism of the lenses; to this end he imagines twenty-one different achromatic systems, in which the principal rays of the solar spectrum are successively united in pairs at the same focus, and in each of these cases he determines by a close calculation the relative foci peculiar to each of the other rays.

In the second part of the *Mémoire*, still more developed than the first, the author endeavours to give a practical character to his work by considering the following problem:—Given an objective, for which we have determined, by experiment, the difference in position of the two foci, in the instance where the image is of the same size as the object; to determine beforehand the distance of the two foci (or what the author calls the *chemical correction*) for any sized image, or in other terms, for any distance from the object.

The author arrives at a very simple formula, which permits of our calculating the photogenic distance of the optical focus of any objective system whatever, for various sized images, provided that we have determined, by experiment, a certain constant quantity peculiar to each objective, or the distance of the two foci in the case where the image and the object are both of the same size.

This *Mémoire* concludes with numerical tables, intended to give, in all circumstances which may present themselves in practice, the value of the *chemical correction*, and of the slight displacement which must be given to each plate, beyond or nearer to the optical focus, to obtain the greatest possible sharpness in the picture. These tables have been verified by M. Bertsch, the eminent photographer.

The author of this *Mémoire* is M. Felix Reynard, of Saint Martin, near Grenoble. The Academy has awarded him a gold medal of the value of two thousand francs.

The second *Mémoire* is written in the German language. Its device is:—*Es irrt der Mensch so lang er strebt.*

The work is in two parts; the first consists principally of the principles of optics.

In the second part, which includes no less than thirty folio pages of numerical calculations, the author, with a zeal and perseverance worthy of all praise, devoted himself to a detailed analysis of the properties of various achromatic objectives composed either of one or many systems of lenses; and in taking into account in these calculations the thickness and mutual distances of the lenses, he determines separately the foci, or points of meeting, of nine species of different rays, at nearly equal spaces amid the various colours which compose the solar spectrum from the ray B to the ray H.

From these researches the author draws practical conclusions adapted to guide opticians in the construction of objectives intended for photography, by indicating certain relations between the distance which separates the optical from the chemical focus for various objectives, and the tint of the coloured fringes which border the images when the eye perceives them in the optical focus.

The author of this *Mémoire* is Herr Carl Miersch, of Dresden, Saxony. The Academy, in recognition of the merits of this work, awarded the author a gold medal of the value of a thousand francs.

At the last meeting of our Photographic Society, the committee reported that, considering the prosperous condition of the Society, they thought it their duty in future to encourage and reward the interesting works and important inventions that might be communicated to it. They propose to establish an annual distribution of medals to be awarded as honorific rather than as pecuniary recompenses, for the most important presentations made to the Society, beside the competitions opened for certain determinate prizes.

The President remarked that it was unnecessary to dwell upon the evident advantages of this proposal, which, while rendering an act of justice, would excite and surely attract to the French Photographic Society the studies and researches of all those, foreigners as well as natives, who could in any department of the art effect an improvement and aid the progress of photography. But, in order to secure all the advantages of the proposal, it would be necessary that the programme should be carefully studied, and its application well regulated.

The Secretary also announced that the committee, in order to impart additional interest to the meetings of the Society,

proposed to exhibit various experimental demonstrations upon the scientific questions connected with photographic phenomena. M. Edmund Becquerel, at the request of the committee, will commence a series of demonstrations at the February meeting of the Society.

It was also stated that the project of connecting a photographic laboratory with the *locale* occupied by the Society had for a long time engaged the serious attention of the committee, but that certain practical difficulties existed which prevented the committee from carrying out this desirable object. When their present lease expired would be the time to select such a locality as would admit of this project being carried into operation.

The Secretary observed to the meeting that the Society had now been in existence eight years, and had prospered far beyond all expectation; and that this prosperity was doubtless owing to the prudence with which its affairs had been conducted. It may not be superfluous to remind English artists that our Photographic Exhibition opens on the 1st of May, and that we hope to see it adorned with some of those charming works the fame of which has reached us, and which form the frequent topic of photographic conversation.

WHOLESALE PIRACIES.

OBSERVING the letter of "Fair Play" in your last week's journal, on "New Mode of Piracy," I think it well to inform you that I have the opinion of an eminent member of the bar, well versed in copyright law, that *this* system of copying is illegal; also, that there is no doubt but a verdict would be given against photographers and dealers for selling copies of *cartes de visite* which have been published *prior*, although registered *since* the passing of the Act 25 and 26 Victoria, sec. 6.

I believe it is not generally known the enormous extent to which piracy in photography is carried on. Having received information from various correspondents that copies of my portrait of a person of considerable celebrity were being sold to a great extent throughout the kingdom, I took the trouble to discover the delinquent. At one wholesale dealer's I obtained his list of no less than 500 various portraits, at a second 559, at a third nearly 700; the stock in the warehouse of the latter must consist of at least 100,000 copies, therefore we may conclude that as many have been palmed on the public as genuine, which of course very seriously injures the reputation and interest of the original photographers.

On taking legal steps against one of these unprincipled dealers, proceedings were stayed in consideration of certain damages and costs, and a discharge to that date given from any further penalty for having sold pirated copies; also, to nearly thirty of his customers, amongst whom were to be found the names of many of the largest and wealthiest silkmongers and drapers in the city and provinces; but it is believed these latter gentlemen were ignorant that they were being supplied with spurious goods. The photographer in one case (who, by the by, claims relationship with royal blood!) also had to pay heavy damages and costs, and was bound over to respect the law for the future. In the two cases which appeared in the *Times*, at the Clerkenwell Police Court, on the 22nd inst., before Mr. Barker, the defendant was convicted, and a penalty imposed of £3 0s. 6d. and costs, £2 2s., in each case. Although nothing could have been clearer than the proofs in each case, defendant's solicitor recommended his client to appeal against the decisions of the magistrate. Wisely, however, the penalties have since been paid.

Were photographers to devote a little time and trouble to their own interests in this matter, they would soon put a stop to piracy. The course to be taken is simple: the proprietor should send some one in his employ to purchase a copy exposed for sale; let him write on the back the name and address of the vendor, time and date, and post it to the

solicitor, with instructions to do the needful, and within a week or ten days the police magistrate will convict the offender. I hear that there are no less than 18 cases now in the hands of the solicitor, several of which will be brought before the provincial magistrates. It is to be hoped that every possible information respecting illegal copying, will be given by respectable dealers to the solicitor of the Association.—Your obedient servant,
A PHOTOGRAPHER.

[We strongly commend photographers to adopt the advice of our correspondent. Prompt and vigorous measures now, will, we hope, speedily put a stop to the piracies which have so long degraded the art, and defrauded able and respectable photographers. We intend to give the fullest publicity to every case of which we obtain information. See page 55.—Ed.]

Photographic Notes and Queries.

OBTAINING CLOUDS IN LANDSCAPES.

SIR,—The use of the flap-shutter, for varying the exposure of foreground and sky, as mentioned by Mr. W. H. Warner, in No. 227 of the *News*, although not new, is perhaps the most simple mode of attaining that object—at least, in cases where the straight edge of the shutter does not preclude its adoption. May I be permitted to suggest a mode of working it which I have found advantageous, in use with the binocular box stereoscopic camera, which I designed about three years since, and which I think will be found free from the objections which would apply to the plan of marking with a pencil line, as described by your correspondent. A small index is attached to the axis on which the shutter turns, and is fixed by a movement of the finger of the same hand by which the flap is held, while the necessary angle is ascertained by looking at the ground glass. The details will immediately suggest themselves to any mechanic. I think, at the same time, that the use of the flap-shutter, in the ordinary form, must always be extremely limited, and thus a means of adapting the line of division to that of the actual view will be much more valuable, and this is not difficult of attainment.—Yours truly,
C. W. SMART.

BOOK PACKETS AND NEWSPAPERS.—The following regulations will affect the postage of photographs:—On the 2nd of February the following alterations will take effect in the rules affecting book packets and newspapers:—1. Book packets sent through the post between places in the United Kingdom, or between the United Kingdom and any of the colonies, which may have been posted either wholly unpaid or paid less than a single rate of book postage, will be forwarded to their destination charged, not as at present with the letter postage, but only with a postage which, together with any stamps which they may bear, will be equal to double the book postage which should have been prepaid. 2. No prints or printed matter will be allowed to be sent in book packets between places in the United Kingdom, or between the United Kingdom and any of the colonies, except such as may be printed on paper, parchment, or vellum. 3. Any newspaper bearing the impressed or newspaper stamp, posted for transmission between places in the United Kingdom, which may be found to have any writing or marks (though it be only a previous address to another person, and that cancelled) either upon the newspaper itself or upon its cover, other than the name and address of the person to whom it is sent, or anything printed upon its cover, except the name or title of the newspaper and the name and address of the publisher, newsvendor, or agent, by whom it is sent, will be charged, not as now with the double letter postage according to its weight, but only with a postage of 2d., being the double postage for a letter not exceeding half an ounce in weight. This charge is to be made for each newspaper written upon or marked, whether sent singly or in a packet of newspapers. 4. A newspaper for any place abroad, which may be found to infringe the rules in the manner described in paragraph 3, will not be forwarded, but will be sent to the returned letter branch. 5. A newspaper received as such from abroad, in regard to which there has been a similar violation of the rules, will be charged, in addition to any postage which may be chargeable upon it as a newspaper, with the postage payable on a single letter from the same country.

Talk in the Studio.

THE RECENT ROBBERY OF LENSES AT THE CRYSTAL PALACE.—Our readers who have already read the particulars of this case, as heard before the sitting magistrate at Lambeth, would notice two advertisements in our last; from Messrs. Negretti and Zambra, offering ten pounds reward for any information regarding the stolen lenses, and another offering two hundred pounds reward from Mr. Restal for similar information. As we are desirous of aiding the cause of justice, and the credit of photography, we wish to call the attention of our readers to these announcements, and to suggest that if the slightest information bearing on the subject be in the possession of our readers, it should be forwarded without delay both to Mr. Restal, the accused, and Messrs. Negretti and Zambra, justice demanding that both parties, in such a case, should be put in possession of every particular relating to it. It will be observed that any one who has, in ignorance, purchased any of the lenses, will not be deprived of them, Messrs. Negretti and Zambra being more anxious to find the real culprit, than to recover their lenses.

OPTICAL ILLUSIONS AT THE POLYTECHNIC.—Our readers who have opportunity will do well to hear Mr. Pepper's "Strange Lecture" at the Polytechnic Institution, which is chiefly devoted to the explanation and illustration of optical illusions, and incidentally contains many interesting illustrations of the nature and properties of light. The great feature of the lecture is the introduction of certain "ghosts," which, in vividness and reality, exceed anything before produced by optical illusions. The exact nature of the appliances is not explained, but there appears to be little doubt that the images are projected by the aid of a concave mirror. How the intensity of illumination necessary is managed is the puzzle, as the spectro appears at times more solid, real, and vivid than the real figure of a man which passes through the spectral images. We can conceive that photographing a ghost would become tolerably easy in this case.

To Correspondents.

- MR. SKAIFE'S PISTOLGRAPH.**—The words "Illustrated Guide, 2nd edition," were left out in the advertisement of Mr. Skaife's Ten Guinea Pistolgraph. This book can be obtained on receipt of 13 stamps, by applying at 32, Sussex Street, Regent's Park.
- NON-ACTIVE GLASS.**—Our report has been requested on several samples of glass. John Martin sends a specimen of brown pot metal, which we have so constantly had occasion to warn our readers against, as permitting considerable quantities of actinic light to pass through. J. W. sends three samples: No. 1 is similar to the above, but much lighter, and therefore even less safe. Nos. 2 and 3 are silver flashed glass. The former is very light, and in the spectroscopie allows many actinic rays, especially about the blue and violet, to pass. No. 3 is perfectly opaque to all photographic rays. EXCELSIOR sends two specimens: No. 1, a piece of the above-named brown pot metal, and No. 2, a piece of good orange silver flashed glass, identical in colour and properties with J. W.'s No. 3. The sample sent by J. B. is of similar silver flashed glass, which is perfectly trustworthy for the window of a dark room.
- PERPLEXITY.**—For glass positives it will be desirable to add a little nitric acid to the bath after treating with carbonate of soda. Or the same result, that is, clean shadows, may sometimes be obtained by adding tincture of iodine to the collodion, until it is the colour of a brown sherry. Regarding the works you name, No. 1 is out of print, and No. 2 is out of date.
- L. L. H.**—You will find much information on the application of photographic lenses to the purposes of the magic lantern in our back volumes. We may especially name page 53, Vol. v., or No. 126. See Mr. Highley's paper on the Magic Lantern and Photography.
- II. KENT.**—The method referred to is recommended by Mr. Maxwell Lyte; we have not tried it ourselves. When you add carbonate of soda to an acid solution at any time, be careful how you cork it up, as, unless the carbonic acid gas liberated can escape, an explosion such as you describe may easily follow. If you adopt the same method again, mix the carbonate of soda and phosphate of soda in a little water, and then pour it into the discoloured silver bath in an open vessel, stirring it meanwhile with a glass rod. We generally use kaolin to decolorise a bath.
- GARIBALDI.**—We cannot with propriety undertake to say which is the best house for obtaining any kind of photographic material; but in the articles you mention, silver and gold, the prices are generally uniform. It is impossible to say where they are kept purest.
- KRUGER.**—Your lens is scarcely quite equal to the production of standing card portraits, and you use too much front light, which gives flatness to the features.
- II. B.**—To obtain a biting surface in glass positives, upon which dry colour will readily adhere, a suitable varnish should be used. The alabastine varnish sold by Squire and Co., or the positive colouring varnish, sold by Newman, will answer the purpose. Colour first on the film, then varnish, and then again apply the dry colours. Should you not be able to obtain the varnish referred to, you may use a coating of turpentine after colouring on the film. This must be thoroughly dry before applying the colour,

and you will find it then adhere without difficulty. Nevertheless we do not like the use of the turpentine.

- II. R.**—Mr. England informed us that he had kept tannin and honey plates some months without serious deterioration. They should, however, be developed as soon after exposure as possible—that is, within a day or two. There is some uncertainty and discrepancy of experience on this subject. 2. The best mode of keeping dry plates is that which will most effectually protect them, not only from the light, but from moisture and atmospheric influences. If packed up in the fashion of Dr. Hill Norris's plates, they should, like his, be made air-tight. 3. Mr. Robinson has given the "May Queen" negative to a committee for the relief of Lancashire. We cannot tell you at present where prints may be had, nor the price. The negative went into the charge of Mr. Delamotte. 4. We prefer camera printing, with wet collodion, for transparencies. If you prefer printing by super-position, use tannin plates.
- F. L. G. K., AN OPERATOR, AN ASSISTANT OPERATOR, A PHOTOGRAPHIC PRINTER, and some others.**—We believe it is now in contemplation to open the Exhibition in the evenings the last fortnight of the season. See our remarks in this week's critique.
- AN AMATEUR.**—We do not remember, at this moment, a description of a changing box sufficiently full to enable you to make one; but they are to be had of most camera makers, and dealers in apparatus. We remember to have seen them in the establishments of Bland and Co., Mr. Hughes, and Mr. Meagher, and are, doubtless, kept by others. We are uncertain of the price. 2. Our own method of coating plates with the tannin solution is to pour on the plate sufficient to cover it; let it rest a minute or two on a levelling stand, whilst we attend to another plate; then pour the first solution off and coat again, and allow the plate to drain. We have no doubt that Mr. Sutton's plan will answer very well.
- JOHN MARTIN.**—Report on your glass in a paragraph above. 2. The electric light is the most actinic artificial light which has been applied to photographic purposes; but none has yet been successfully, or generally, applied commercially. 3. The plan described is scarcely suitable for the manufacture of oxygen on a small scale. 4. Three parts of chlorate of potash, and one of oxide of manganese, are good proportions for the manufacture of oxygen. 5. About four cubic feet of oxygen, and the same quantity of carburetted hydrogen will be consumed in an hour.
- A. B. C.**—Moule's night light is chiefly used for producing glass positives, and we have seen some pretty good ones so produced. Of course there is some little difficulty in obtaining sufficient light on the sitter without dazzling the eyes. We cannot tell you whether it is much used or not. 2. Polysulphide of potassium, or liver of sulphur, should be used for precipitating the silver from the residues of the sink. If you do a large business it will be quite worth while to save such residues.
- JOHN HAWKE.**—We are obliged by the charming cards, and also by the satisfactory information as to lens and collodion. We shall "make a note of it."
- D. M. A.** sends us, amongst various hints which we shall note and remember, a suggestion for the use of a solution of iron in place of tannin for dried plates. He states some experiments lead him to think that it would be successful. We fear it would be somewhat unmanageable, and that the plates would not keep well. It will be important to remove all free nitrate.
- E. L. LOCKE.**—Methods of dissolving silk to use instead of collodion have before been suggested, but have not come into practical use. By using proper care in the manufacture of collodion it is quite possible to obtain a very adherent and strong film.
- R. S. S.**—There is unquestionably a want of force about the standing figures, but whether it is due to having too much light stopped overhead we cannot with certainty say. There appears to be too much diffused light and too little direct light. The light wants concentrating so as to reach the sitter more directly from one source, and thus produce more definitely marked lights and shadows. Five or six feet opaque overhead, with a little more semi-opaque may probably answer very well. The standing figures appear over-exposed, and that will destroy contrast, however well lighted the figure may be.
- A. B.**—We will write shortly.
- COLOMBO.**—We do not know of any efficient means of restoring faded prints. Immersing them in a solution of chloride of gold has been suggested, but we have not tried it. Those which went down in the *Colombo* have been submitted to so many agencies which would act on silver prints that it is difficult to trace the cause of the discolouration and fading. When warmed they smell strongly of sulphur.
- G. R.**—For copying oil-paintings use a freely bromized collodion. Then expose for the darkest or most non-actinic parts, leaving the lights to take care of themselves. You will not lose detail in this way. Mr. Thurston Thompson, who has produced some of the finest copies of paintings ever issued, uses half as much bromide as iodide.
- S. JONES.**—We are not certain that we decipher this correspondent's signature, who enquires how long the acetate of soda and gold bath may be used. There is no especial limit but the bath becoming inert or exhausted; but it is well to use a little at a time and not use it very frequently, as it becomes of an uncertain strength and renders its time of working irregular. Slow toning may depend upon an inert or exhausted condition of the bath, upon cold weather, the quality of the paper, &c.; give paper, highly albumenized, toning more slowly than others. You may safely tone twenty card prints in one ounce of hypo, dissolved in five or six of water. A toning bath of hypo and gold which has been in use for six months is altogether unsafe, and the prints are not likely to stand. We do not require any fee for our advice in this column, it is always freely at the service of our readers.
- W. FOX.**—Thank you for your hints, of which we shall make a note. Articles on "Art-Photography and its Critics," on "Harrison's New Globe Lenses," "Scientific Gossip," and a variety of others are compelled to stand over for lack of space.
- AMATEUR, DRY PLATE, ALEC. ARNSTEIN,** and several other correspondents in our next.

Photographs Registered During the Past Week.

ART-PHOTOGRAPHY AND ITS CRITICS.

THE majority of the art-critics have shown an amusing agreement in condemning art-photography, as displayed in the Photographic Exhibition this year. Critics do not often endorse each other, but "when they do agree, their unanimity is wonderful." It is true they vary as to the precise grounds of their condemnation, but they agree in attacking the art wherever it seems most likely to innovate upon what they conceive to be the legitimate province of the artist, wherever it seems likely to produce pictures, or something more than studies, which "may be taken as memoranda for the use of artists." It is the old story, which we had thought dead and decently buried, revived again. Photography is to be a servant of servants; it may hew wood and draw water, or do other mechanical labour; but it must not presume to act as having attained its freedom in the guild of art.

Accordingly, it is against the attempts to make pictures we find the greatest rancour is directed, and Mr. Robinson's noble composition, "Bringing Home the May," has been the especial victim. In the *Illustrated News* we are informed that "photographers only can estimate the difficulty of selecting and posing the different models, arranging and uniting the different studies, and toning into harmony such a work as this; and, perhaps, only artists can fully understand how completely this labour is thrown away. What have we here?—a funeral rather than a gleeful procession." It would not require an artist to discover the difference between a funeral and a gleeful procession; but it certainly would require an art-critic to discover any suggestion of a funeral in the noble picture referred to. Another remarkable fact is discovered by this critic, which photographers will be surprised to learn, is, that "photographers seem disposed to force the power of their lenses more than heretofore; hence the curvature in the lines of architecture, which is becoming so frequently perceptible." Our own conviction, which we held in common with the majority of photographers, was, that this curvature, at one time almost universal, was, since the invention of a lens absolutely free from such distortion, becoming very rare. The remark is made, it is true, whilst speaking of Mr. Bedford's pictures, and charging them with this fault. It happens that Mr. Bedford, in working in the East, used simply the single lens, which, in architectural subjects, gives this curvature; but to base on this fact a statement that such curvature is becoming more common, simply displays ignorance of the real facts. Amongst some just and discriminating remarks, we have many further misuse of terms, displays of ignorance of the art, which are sufficient to show the worthlessness of the general opinion. We have, for instance, talk about "the inevitable focal distortion," whatever that may be; about the enlargement of the "spectrum," by which is meant not a spectrum at all, but the point of light in the eye. We have familiar talk about the photozincography of Col. James, and the chromo-carbon printing of Capt. Scott as distinct processes; and more to the same purpose. It is somewhat amusing to find that the

objections of this critic are little more or less than wholesale plagiarism from Lady Eastlake's article in the *Quarterly Review* on Photography, some half dozen years ago, and which, we need scarcely inform our readers, was a very different thing to the photography of to-day. The critic in the *Illustrated* reached the end of his article and the climax of absurdity together by informing his readers that Mr. Breese exhibits instantaneous stereographs in which is a "painted moon." We commend to him the task of painting—in lights into any photographic transparency on glass, without the added difficulty of making his "painting" stand the test of the stereoscope.

The *Daily News* has always been distinguished by its just and appreciative view of photography; but the advance of certain phases of photography seems to have startled it into injustice. We are told that photography "continues trenching closer and closer upon the territory of the artist proper; that we rub our eyes as we ask ourselves whether all this is art or art manufacture, and whether the taste for the photograph indicates a healthy feeling for art in its nobler forms, or merely a rage for having the eye tickled, as it were, with close imitations." And we are further told that other "instances of a vulgar and degrading tendency of photography in some hands" is found in pictures of "the sea struck by the instantaneous process into a sort of petrified ploughed field." We are here willing to put against the dictum of the critic the opinion of the President of the Royal Academy, Sir Charles Eastlake, who when he first examined an instantaneous stereograph of the sea, exclaimed that, compared with this, he had never before seen the sea delineated by any method. On the production of subject pictures, the *Daily News* is more intolerant still, as "a development of the art more offensive than any other." "Bringing Home the May" is styled a "particularly conceited attempt of this kind;" the budding May is called "ridiculous looking stuff, more like sponge than hawthorn blossom." How a good photograph of May blossom should look like something else, we leave the critic to explain; but we may remark that he has evidently fancied that the photograph was not from nature, since he speaks of such pictures as being produced from "properties and living lay figures." The last time the *Daily News* noticed an exhibition of photographs, Mr. Robinson's composition pictures were selected for especial praise; they are styled "simple," "natural," "pleasing," "beautiful;" and it was hoped they "would bring him the fame he deserves."

The *Illustrated Times* attacks the same phase of photography, and informs photographers that they mistake their vocation in "making subjects out of dressed-up figures, and sundry shrivelled greenery and rock-work." In this remark we agree with the critic; but we are bound to add that we have not seen any pictures produced from such materials in the present Exhibition.

Various other reviews of the exhibition have appeared with criticisms of similar tendency, the only thoroughly genial and appreciative notice appearing in the *Morning Post*.

We may mention here also a drearily funny article in a recent number of *Chambers' Journal*, with the title of "The Modern Priests and Temples of the Sun." The chief idea that strikes us in reading this article is wonder at the amazing misinformation it contains. The ignorance of the writer appears to be of that character which has been styled as "not only comprehensive and vast, but very elaborate and minute." We are told, for instance, that a photograph always inverts the figure, making the right hand the left, &c., and that "this diabolical perversion was doubtless invented by photographers," &c.; for what purpose do our readers think? The writer says, "in order to compel us to have *cartes de visite* taken!" This class of picture being, it is added, the only kind free from this perversion. We are told that a photographic studio "poisons the air" in the neighbourhood where it exists with the fumes of collodion! The writer affirms his conviction that there is little difference between a photograph done by the best artist and a sixpenny glass positive. This latter remark, by-the-by, explains the first. The writer has doubtless qualified himself for writing on the subject by obtaining a portrait, "frame and glass included, for sixpence." There are a great many similar complaints equally silly and equally untrue. In a case of this kind some allowance must of course be made for the writer's desire to be funny: there might easily have been more real humour, however, as well as truth.

Photographers generally look with great interest for criticisms which are supposed to represent public opinion. When these criticisms are honest and free from warp or bias, they are often valuable as presenting suggestions and hints from a fresh and untechnical point of view. Many of the remarks in the notices of the daily papers to which we have alluded are interesting and discriminating, especially when accrediting the art with its acknowledged unparalleled powers of literal reproduction. But where it threatens to trench upon the province of what they are pleased to term "art proper," the animus at once becomes apparent.

We have another criticism on art photography coming from another quarter, which will be found on another page, and which we cannot reproduce without a word of comment. Our esteemed friend, Mr. Sutton, recently communicated to the Photographic Society of Scotland a paper "On some of the Uses and Abuses of Photography," which will be read with much interest. But there are certain portions of the paper against which we must protest, as being, in our view, repressing and discouraging to the earnest and ambitious photographer. Mr. Sutton objects to picture-making by photography. He says:

"What you want in a work of art is not an exact and truthful resemblance of a group of natural objects, however cleverly arranged and lighted, but a reproduction of such objects, or of a new combination of such objects, according to impressions which they have produced upon the human mind. The first chalk drawings of a schoolboy upon a wall are, in my opinion, more admirable, from the human interest which they possess, than the finest view of inanimate natural objects upon the ground glass of a camera obscura."

We cannot here enter into the whole question, upon which we have often before expressed our opinion; but whilst we demur to the canon of art laid down, we also affirm that if it were true, photography can largely fulfil its conditions. First, we demur to the canon that an exact and truthful resemblance of natural objects is not wanted in a work of art, but that somebody's impressions of such objects constitute art. Art has many phases: high art or heroic art must present nature idealized and ennobled, or at least in the highest and loftiest aspects of which it is capable. We do not assert the power of photography here. But art also possesses phases in which exact and truthful resemblance are the highest qualities, and here photography claims the power to produce genuine works of art, capable of giving pleasure which neither palls nor diminishes. Where photography most fails in producing works of art is just where

it fails being truthful. If it could produce colour as well as form, the most skilful pre-Raphaelite might strive in vain to produce works of art equal to the camera. The one lesson which great artists have ever pressed on the attention of students has been to present nature truthfully, and not in the conventional garb of their own impressions.

But, in the second place, photography can and does to some extent present nature according to the impressions of the photographer. Else, how is it that each photographer has his style or manner as distinctively as various painters? The photographer with a coarse appreciation of natural beauty will give us coarse photographs, wanting entirely the delicate detail, the soft gradation, the tender aerial tints which render the more skilful artist's productions so charming. As to almost all the qualities which constitute style, at least in monochrome, the matter is quite under the control of the photographer. It is true, except with very bad treatment, the lens will not generally give the bad drawing in which some painters indulge; but, as regards grouping and arrangement; point of view and choice of light; the production of flatness or relief; delicacy and detail or vigour and suggestive masses, &c., the effect is as much under the control of the photographer as it is in the hands of the painter. One photographer will make a beautiful picture, and another an ugly portrait of the same sitter; one will tell a story, and the other will produce an unmeaning group with the same models; one will make a landscape look a place to be shunned, and another will make of the same place fairy land. In short, each will present his subject largely as it has produced an impression on his own mind.

We do not make any arrogant claims for photography. We know there is much sad inartistic stuff produced; we know that its best phases cannot rival the highest phases of art. We know it lacks the glorious charm of colour; we know that the finest monochrome must be to the many-lued scenes of nature but—

"—As moonlight unto sunlight,
And as water unto wine."

But we know also that photographs may be pictures, genuine works of art, refreshing the eye, and largely satisfying us with the recollections of beauty they recall. We esteem Mr. Sutton highly, and respect his opinions; but we cannot but regret that an authority so highly regarded should thus slight an important phase of the art. Outside criticism of this kind we can smile at; but when the wound comes from within the charmed circle, we cannot but recall Byron's lines:—

"Keen were her pangs, but keener far to feel
She nursed the pain that impelled the steel."

ARTISTIC COPYRIGHT.

A MEETING of painters, engravers, &c., was recently held at the French Gallery, Pall Mall, for the purpose of considering the best means of obtaining a more effective copyright in engravings. As the subject is interesting to photographers, and we wish to make one or two remarks on the subject, we condense from the daily papers a brief account of the proceedings:—

"To illustrate the facility and success with which the finest and most costly works on which a great amount of combined genius, skill, capital, and labour may have been expended, both by the painter and the engraver, pirated copies of the following subjects, made by photography, zincography, lithography, and the anastatic process, were exhibited in the room side by side with the original engravings from which they had been taken:—Portrait of the Empress of the French, engraved by Danguin; the "Parce Somnum rumpere," engraved by Raphael Morghen; Landseer's 'Monarch of the Glen'; Hunt's 'Light of the World'; Rosa Bonheur's 'Horse Fair,' &c. It is almost unnecessary to say that the genuine production and the spurious imitation in every case so closely resembled each other as to be

scarcely distinguishable, although the fair price of the one might be half a guinea or a guinea, and the other could easily be sold for a shilling.

"In introducing the business, the Chairman explained that the Act relating to Works of Art passed last Session recognized the painter's claim to the copyright of his pictures for a given period, and the photographer also enjoyed legislative protection, but the property of the engraver was still left wholly insecure.

"Mr. FRITH (who was unable to be present), in a letter, said:—"The recent Act is efficient as regards the copying of pictures, but while the remedy of the publisher, who has paid liberally for a copyright, is not secured to him by law against photographic piracy, he will be neither willing nor able to pay for copyright as heretofore; and, if that should happen, the class of art I practise will almost cease to be followed. It is to me incredible that the law should give a quick and cheap mode of redress to the photographer whose works are pirated, and refuse it to the publisher whose stake is so large, and the object of whose speculation is often so creditable."

"Mr. GAMBERT, art publisher, addressed the meeting, forcibly pointing out the peculiar hardship under which his class laboured by having their best engravings, produced at a heavy outlay, pirated by any man who had a little skill in photography, and could muster 6d. to invest in a few chemicals. The injustice of this was all the more flagrant inasmuch as the photographer who thus unscrupulously robbed the engraver was himself amply protected against piracy on the part of his rivals. No publisher would venture to give commissions, involving thousands of pounds, to artists like Mr. Frith or Mr. Holman Hunt, while the law left their property an easy prey to such unprincipled depredators. Thus, art must be discouraged, and the public would suffer.

"Mr. Herbert, R.A., Mr. E. Nicholls, R.S.A., Mr. Thomas Landseer, Mr. Redgrave, Mr. Tom Taylor, and other gentlemen, having also addressed the meeting, a series of resolutions was unanimously adopted insisting on summary redress against this particular class of piracies by proceedings before any two justices of the peace, together with the improvement and consolidation of our own laws relating to artistic copyrights, and the expediency of an assimilation of the codes of the great European countries on this matter. The business closed with several formal votes of thanks."

We most cordially agree with the proprietors of engravings in the importance of obtaining a more swift, simple, and sure remedy against piracy, than at present exists in the engraving copyright Acts. But we cannot help pointing out a fallacy which we are surprised to find generally held and expressed without contradiction at the meeting. Mr. Frith, for instance, says, that the recent law protects pictures but not engravings. But, does not he perceive that if the picture be protected, the engraving of it must be also secured by that very protection? The owner of the copyright in a picture is protected from copies being made by any process whatsoever. He alone has the right to photograph, engrave, or duplicate that picture by any means, and a copyright exists in each copy by any method. If, therefore, he issued an engraving, and that engraving be copied by photography, such copying becomes an infringement of the copyright in the original picture. This of course only applies to pictures enjoying the protection of the recent Act, and does not apply to many valuable engravings already in existence, the property in which is injured by piracy, and in regard to which a more simple remedy is imperatively required. We wish those concerned all success in securing such a remedy. For, whilst we are deeply interested in the dissemination of cheap art, we have no sympathy with those who would secure it by the sacrifice of private interests.

PHOTOGRAPHIC EXHIBITION.

AWARD OF PRIZES.

THE adjudicators appointed by the council of the Photographic Society to award the prize medals for the best contributions representing six phases of the art, have just tendered their report. We stated in our last that, regarding the majority of the medals, little hesitation would exist as

to whom they should be awarded to; but that in regard to landscapes the task would be one of some difficulty. We find from the report that our own views have been shared by the adjudicators. They state that in reference to four of the medals they had no hesitation in coming to a conclusion; that in portraiture the merit was more divided; and that in landscape it was almost equally shared by many contributors. Although it is probable that in regard to some of the decisions opinions will vary, we cannot but think that on the whole the awards will give satisfaction. They stand as follows:—

M. Claudet, for the best portrait or portraits.

Mr. F. Bedford, for the best landscape or landscapes.

Col. Stuart Wortley, for the best instantaneous picture or pictures.

Viscountess Hawarden, for the best amateur contribution.

Mr. H. P. Robinson, for the best composition picture from life.

Mr. Thurston Thompson, for the best reproduction.

We must delay further criticism of the exhibition until our next.

SILVER IN THE WHITES OF ALBUMENIZED PRINTS.

BY JOHN SPILLER.

WITH reference to a former communication which you did me the honour to insert in the PHOTOGRAPHIC NEWS (vol. vi. p. 470), I beg leave to request that you will permit me an opportunity of resuming the subject, and of describing some of the results met with in a course of experiments directed to the removal of traces of silver from the whites of albumenized prints. The difficulties to be overcome appear greater, as one chemical agent after another is tried, without accomplishing the desired result; and the object of my addressing to you the present memorandum, is rather to report progress, than to record complete success.

I have already stated, that a second immersion of the print in a fresh solution of hyposulphite of soda, is capable of removing a small proportion of the insoluble silver compound, and that this is the case also when a treatment with iodide of potassium is resorted to. Since the date of this announcement, I have tried the action of a great number of soluble salts, particularly those of ammonia, many of which are distinguished for their power of dissolving the ordinary silver precipitates. Amongst other salts, were the carbonate, acetate, citrate, and phosphate of ammonia; the alkali itself and phosphoric acid separately; tartaric acid and Rochelle salt. None of these were capable of removing the last traces of silver, and there was so little advantage gained by their employment as auxiliaries to the fixing bath, that I have been led to try the cautious use of cyanide of potassium. By immersing the prints in very dilute solutions of the cyanide, I have succeeded certainly in removing every trace of silver from the whites, but always at the expense of the shaded portions of the picture, for so readily soluble are the metals, silver and gold, when in this extremely fine state of division, that it will, I believe, be practically impossible to limit the solvent action in the manner intended. By operating upon over-printed proofs, on albumenized paper, I obtained pictures which were presentable, but I do not consider that the details were so delicately rendered as in the case of other prints obtained from the same negative by ordinary treatment. The albumen itself, at this stage of the process, does not appear to suffer by immersion in aqueous cyanide of potassium, of the degree of concentration (one grain, or less, in the pint of water), that would be requisite for this particular application.

Terro-cyanide of potassium has the property of dissolving many insoluble compounds of silver, but, according to my experience, is of no value for the purpose at present in view.

In your report of the proceedings of the Marsilles Photographic Society, November 8, 1862,* allusion is made to the

* Vide PHOTOGRAPHIC NEWS, vol. vi., p. 536.

proposal of M. Messnier, to employ the sulpho-cyanide of ammonium as a fixing agent in photography; and your correspondent further states, that the subject has been referred to a committee, to inquire into, and report upon the chemical value of this suggestion. Pending the decision of the French investigators, it may not be out of place to describe some of the characters of this salt, which have presented themselves in the course of preparing and employing this substance as a fixing agent.

There are three processes available for the preparation of sulpho-cyanide of ammonium:—Synthetically, by acting upon hydrocyanic acid with excess of yellow sulphide of ammonium, and evaporating to dryness over a water bath. Or, by virtue of double decomposition, on dissolving in a small bulk of water equivalent quantities of sulpho-cyanide of potassium and sulphate of ammonia, and adding alcohol or methylated spirit, when the sulphate of potash is precipitated, the sulpho-cyanide of ammonium remaining in solution. The third plan is but a modification of the second, and consists in fusing together the yellow ferro-cyanide of potassium with half its weight of sulphur, dissolving in water, and treating the crude mixture of the sulpho-cyanides of potassium and iron first with sulphide of ammonium to precipitate the iron, and then with sulphate of ammonia and alcohol as before. It is necessary to take care to exclude the presence of free sulphur and hydro-sulphuretted compounds from the products obtained by the first and last of these methods; for, unless perfectly purified, the salt is apt to discolour the whites of the photograph. The crystals obtained on evaporation are transparent and colourless, but the aqueous solution seems liable to undergo a gradual decomposition accompanied with the production of a yellow or reddish colour. The solution, when mixed with nitrate of silver, gives at the first moment of contact a bulky white precipitate of sulpho-cyanide of silver, which, left to itself, soon assumes a granular character, or becomes distinctly crystalline; this precipitate is, however, readily dissolved by an excess of the ammonium salt, and the addition of a soluble chloride to the solution yields no precipitate. Both the chloride and iodide of silver are to some extent soluble in the sulpho-cyanide of ammonium, but not nearly so freely as in cyanide of potassium or hyposulphite of soda. On testing the power of this salt in removing the traces of silver from the whites of albumen prints, I find that it succeeds perfectly; but, at the same time, it must be confessed that the sulpho-cyanide of ammonium is not likely to become a cheap commercial article, and on this account its general use as a fixing agent must for the present be seriously impeded.

We learn from the interesting extract from the *Bulletin de la Société Française de Photographie*, which you printed last week, that the eminent French chemists, MM. Davanne and Girard, have resumed their investigation of the compounds formed by the action of nitrate of silver upon albumen. Referring to the announcement I made in your columns on the 3rd October last, they claim the prior publication, in the year 1859, of the fact of silver being contained in the unexposed parts of albumen prints; and, on looking more fully into the matter, I concede to them the merit of having first made this observation; but it must, on the other hand, be allowed that their statement refers to a mode of conducting the fixing and toning processes which is now obsolete, which seldom gave pure whites; and, according to their own description, the silver compound was faintly visible on the paper, and sometimes even was slightly affected by light.* This is certainly not the case with the photographic surfaces I have examined; and, further, I do not coincide in their opinion that the compound under discussion is "probably a sulphide," since the very existence of the silver was discovered by the sulphide of ammonium test, and the production of the brown sulphide on moistening the pure whites with this re-agent must surely be the result of a chemical change. If the exposure of a sensitized sheet

be delayed until it has commenced to assume a visible discolouration, or the print be fixed in hyposulphite of soda without previously removing the whole of the free nitrate of silver, we obtain a condition of surface, to which MM. Davanne and Girard's description is more nearly applicable. These gentlemen are of opinion, moreover, that the presence of the argento-albumen compound is not likely to affect the permanence of the photograph, and so have not been led to study the means of removing or decomposing the same.

PRINTING DIFFICULTIES.

BY A PHOTOGRAPHER'S ASSISTANT.

SANGUINE as my views are respecting the glorious future of photography, I feel firmly persuaded that the art must ever remain unfettered by fixed rules or formulas, for it will not condescend to be governed by any unalterable number of grains, pennyweights, or ounces, imperative in its demands. It requires the careful hand and intelligent observant mind to guide its ever-varying operations to a successful issue. The above remark is offered as a caution to photographers, who may feel inclined to think that the science of sun printing is at length reduced to a mechanical operation, and, as such, may be entrusted to any blunderer to perform. Although the results I have described were arrived at ere I jumped at conclusions, I deemed it prudent to sit me down, and materially assisted by a soothing "weed," mentally went through the experiments again, the result of these cogitations was a complete modification of my former impressions concerning toning action, so that I am about to start a new theory, powerfully supported by practical, and I may almost venture to add, conclusive proofs; but, ere I proceed to explanations, it is necessary to show the conditions necessary to secure perfect prints, without the necessity of much over-printing. The print on the surface of highly albumenized papers (for reasons before given) is composed chiefly of albuminate of silver. This salt, though more stable than the chloride of the same metal, unfortunately happens to be less sensitive to the influence of actinism; it therefore necessarily follows that prints executed in a dull light must be attended with results not very desirable; there is found wanting that regular gradation of tone, that must be present ere a picture can be pronounced perfect, the light penetrates the shadows, but, its reducing power is not sufficient to act through the semi-opaque portions of the negative that represent the half tones. Hence we have harsh and unsightly contrasts, but the evil rests not here, a bright light possessing the strongest powers of permeation is enabled to produce a deeper deposit by its reducing influence, than can possibly be effected by the weaker actinic rays; hence, in the latter case, provision must be made to meet the difficulty, and this might be effected in two ways; first, by judicious printing; secondly, by a modification of the bleaching or reducing power of the toning solution. If the first-named method be adopted, we must carry the printing in dull light much further than will be necessary in a brighter one, because the reduction, deep as it may appear to the eye, is too slight to bear much bleaching; the reduced film is weak and superficial, whilst the print produced by a bright light, though apparently the same depth, is, in reality, considerably deeper; the light penetrating the minute interstices causes a greater depth of reduction, without the fact being made apparent to the eye; in this case we need go but little further in printing than is required in the finished picture; and if the toning bath is made to suit the latter, it would be found that both classes of prints, if toned together, would exhibit but little difference in their appearance. If we have bright weather, a little over-printing is of slight importance; it is during the dull seasons of the year that the difficulty is most felt. We wish to get through the largest possible number of prints daily, to meet the urgent demands of customers; and, consequently, any method that will effect that object is valuable. As I am still

* Vide PHOTOGRAPHIC NEWS, vol. iii. p. 233.

speaking of highly albumenized papers,* I would strongly advise those who prepare those papers to increase largely the chloride salts employed, for from this source alone we may expect to obtain the necessary conditions of sensitiveness, combined with softness, both matters of extreme importance when printing with a dull light; and to prevent reduction in toning, let the solution be decidedly alkaline. The bath will work very much slower—a matter of little consequence, as this operation may be conducted at any hour of the day or night, so that time is actually gained, as it removes the necessity for printing deeper than when the reduction is produced by a bright light. Direct sunlight, in my opinion, should at all times be avoided for portraiture, save when printing from a strongly contrasted negative. But let the light be strong or weak, more particularly with the latter, the strength of sensitizing solution should never be below 80 grains. Nor should it exceed 85 grains per ounce; and the time of floating should be at least ten minutes; the more prone the paper is to incaliness, the longer should be the floating, by which, in so strong a solution, the albumen cannot be injured. The sensitizing operations should be conducted in a warmed room, and the paper allowed to dry spontaneously; but if circumstances should render it necessary to dry before a fire, we must be observed to avoid doing so before the paper has become surface-dry; for, during the process of drying, the solution upon the paper's surface divides, and towards numberless centres the surrounding atoms are drawn by molecular attraction, forming small globules, which, on removal by rapid evaporation, leave indentations which render the paper quite unfit for printing purposes. If these instructions are strictly and intelligently followed, I believe those who practice them will admit the correctness of a statement made in a former letter—viz., that a clear print may be produced on every paper in the market if its requirements are carefully studied; for, in my experience, I have found that every paper requires a separate or modified treatment; and, as the various samples of gold are subject to changes in the quantities of acid they hold in combination, no fixed formula can be given to produce the necessary qualification for satisfactory toning; but the following explanation, on toning action, will enable anyone to manage his toning solution under all circumstances, that is to say, when carbonate of soda is employed.

Other mixtures will engage my attention, after the completion of this paper, if circumstances permit.

(To be continued.)

THE ADVANTAGE OF A STRONG NITRATE OF SILVER BATH FOR SENSITIZING ALBUMENIZED PAPER, DEDUCED FROM A CONSIDERATION OF THE PHILOSOPHY OF ITS ACTION.

DEAR SIR,—For a comprehensive view of the subject I have chosen for my present letter, I must shortly recapitulate what I have already stated in former communications.

The discoloration of the nitrate bath which takes place when sensitizing albumenized paper, is due to the solvent power the water exercises upon the dried albumen; therefore, in proportion to the power, and the time given for its action, so must the brilliancy of surface be impaired; any means that will mitigate or destroy this power, either previous to, or during sensitizing, must consequently be beneficial. Albumen in its *normal* state being capable of coagulation by various means, it was erroneously assumed that the same means would produce the same effect on it when in a *dried* state. Heat and alcohol were therefore employed, and as by their means the discoloration of the nitrate bath was materially diminished, it was supposed that they had destroyed the solvent power of the water by rendering the dried albumen

men *insoluble*, as insolubility was a known accompaniment of coagulation.

The rapidity with which any substance soluble in water is dissolved in it, is in proportion to its more or less hydrated state at the time it is submitted to its action; and the sole benefit derived by ironing the albumenized surface of the paper with a hot iron, arises simply from its desiccating the dried albumen, and thus rendering it more difficult of solution. The addition of alcohol to the bath, from its not being a solvent of dried albumen, merely serves the purpose of mitigating the solvent power of the water. Heat and alcohol have themselves no direct action whatever upon dried albumen; they *cannot* coagulate it, as it is incapable of being coagulated, and *they do not even render it insoluble*; consequently, they only enable the nitrate of silver to act more energetically, from its not having so much antagonistic force to contend against. The benefit also attributed to floating the albumenized paper upon alcohol previous to sensitizing, *exist therefore only in imagination*, having no foundation in fact. Seeking agents for the coagulation of a substance which is not capable of it, and attributing the benefits derived from their employment, to a cause which has not any existence, must necessarily retard the advancement of our knowledge, as the real philosophy of their action is thus not only misunderstood, but attention is also diverted from that of the action of the nitrate bath.

In the sensitizing bath, we have two *antagonistic* forces acting upon the albumenized surface of the paper; the water having power to dissolve the dried albumen, and the nitrate of silver to render it insoluble, the power of either of them is therefore capable of being diminished to any extent by increasing that of the other, and *vice versa*; thus, it is possible to *wholly* overcome the solvent power of the water by *sufficiently increasing the quantity of nitrate of silver*.

Any solvent power must, according to its strength and time of action, impair the brilliancy of the albumenized surface of the paper, therefore the quicker the dried albumen can be rendered insoluble, the more brilliant will be the prints. There is no doubt in my own mind, that the conversion of the dried albumen and salting chloride into albuminate and chloride of silver *can be rendered instantaneous* by the use of a strong sensitizing bath; and I infer, upon philosophical grounds, that by using one very much stronger than any at present employed, say 250 or more grains to the ounce, a mere drawing of the previously desiccated paper across the surface of the bath will accomplish it.

Sensitizing the albumenized surface, by merely drawing the paper across the nitrate bath, affords the solution no time to penetrate its substance; and the image being thus purely on the surface, must necessarily be more brilliant than it would otherwise be. I think we are perfectly warranted in assuming that the more superficial the sensitized surface can be rendered, the easier can the toning and fixing be accomplished. I believe, therefore, that prints obtained upon albumenized paper thus sensitized, will not only have the utmost brilliancy and vigour which albumen is capable of offering, but will also be rendered more permanent; and that not only less washing will be requisite, but, less silver will be wasted, from there not being so much unused free nitrate to get rid of.—Yours truly,

GEORGE PRICE.

Mornington Road, New Cross Road, Deptford.

ON SOME OF THE USES AND ABUSES OF PHOTOGRAPHY.*

BY THOMAS SUTTON, ESQ., B.A.

GENTLEMEN,—Your Secretary having done me the honour to ask me to prepare a paper on some subject connected with photography, to be read at a meeting of your Society, I have with much pleasure acceded to his request, and put together the following remarks on some of the uses and abuses of photography, in hopes that they may attract your attention to a

* The lighter samples will be treated on in their turn.

* Read before the Photographic Society of Scotland, January 13, 1863.

new use of our favourite art, which I will endeavour to describe, and also excite a profitable discussion on some other applications of photography with which you are already familiar.

I have now been ten or twelve years closely connected with photography, and have watched its progress with the interest one feels in a favourite hobby. During that time, as successive new steps have been taken in the art, I have endeavoured to weigh their importance, and predict their future effect. Sometimes I have been wrong, and sometimes right, in these estimates which I have formed of the probable practical value of new suggestions and processes; and it is interesting and useful from time to time to consider the course which improvement has taken, and the amount of success and popularity which certain branches of the art have achieved, and the comparative failure of others.

I will endeavour to call your attention, in the first place, to the present commercial aspect of photography as compared with that when I commenced editing my *Photographic Notes*, about seven years ago.

Photographic portraiture upon collodionized glass plates, and positive printing upon albumenized paper, were then, as now, the most important commercial branches of the art; while the sale of large views of even the most celebrated and interesting places was comparatively unremunerative. The stereoscopic slides were also at that time becoming important; and the London Stereoscopic Company, whose operations are now so extensive, was founded. But the portraitists were not then so busy as they are now; and, with the exception of a few leading firms, who did their work in the best style, only very moderate incomes were made. I have often at that time spent fine mornings in the glass rooms of really clever photographers, living in good situations, without seeing a sitter, and have wondered how they contrived to make ends meet at the end of the year. But things have greatly altered since then; photographic portraiture has now become a much more profitable occupation, and to be long without a sitter is a sure sign of incapacity, or some obliquity or vulgarity on the part of the operator. There is now a great and increasing demand for small portraits; and if a man cannot get a living by taking them, it is *his own* fault, and the sooner he finds out the reason the better.

The following seem to be the chief reasons why photographic portraiture has received such an impetus, and why it has become at present the most important use to which photography is applied:—

At the time to which I allude, positive printing was in a very unsatisfactory state; and I am sure that if the card portraits of the present day were printed as badly as the paper portraits were seven years ago, there would be but a small demand for them. I think I am right in tracing to the improvement in the printing process the chief cause of the impetus which has been given to photographic portraiture. Thus, as soon as photographers could print properly, and show people beautiful things, persons of distinction were not ashamed to have their portraits taken and exhibited, until at last Mr. Mayall obtained permission to take card portraits of the members of the Royal Family, and sell them to the public, which permission is one of the choicest instances of good nature on the part of a sovereign recorded in history; for photographs are rarely flattering, and were certainly not so in the present instance. As soon as card portraits of the Royal Family of England could be obtained for a couple of shillings, it is not surprising that other sovereigns followed the example, until at length albums and card portraits came into general esteem.

The most important and remunerative practical use to which photography has been put, is that of taking miniature portraits of distinguished people, and selling them at a price which puts them within the reach of all. How highly interesting it is to look over an album filled with unerring portraits of the ruling sovereigns, and celebrated men and women of the day! What an advantage the present generation has in this respect over those that have preceded! and what an advantage future generations would have in studying history, if *permanent* photographs of the leading men, whose exploits are recorded, could be bound with the volume! It only remains to give the last finishing touch to the carbon-printing processes of Pouney or Joubert to render this possible.

But there is another element of the success of the card portraits which must not be overlooked; and that is their small size. Let photographers carefully note the fact that those branches of their art which have succeeded commercially, consist in the

production of *small* pictures—stereo-slides, for instance, and card portraits; while the large views and large portraits have been a comparative failure. I believe this will always be the case; and although there may, perhaps, always be a certain small demand for large things, yet the professional photographer will, probably, as a rule, find it most to his interest to bend to the convenience and taste of the public for small and inexpensive portraits and views. It is not improbable that a fashion for card views may shortly spring up, and become a remunerative business; if that should ever happen, I advise photographers to multiply small negatives from a large positive print. A vignette-d print from a panoramic negative 10×6 might be copied on a reduced scale, and large numbers of small flat negatives taken from it, from which prints of the card size could be produced in abundance to meet any demand.

Next in importance to card portraiture and card views, comes the use of photography to artists, first in assisting them in the production of works of art, and secondly in multiplying correct copies of paintings, drawings, and sculpture. But I cannot agree with those who think that pictures can be successfully built up or composed entirely by photography after the manner of Rejlander and Robinson. According to my taste, everything that I have seen done by these gentlemen in this style has been a failure, and has afforded increasing evidence of what every true artist knew before to be impossible, and opposed to correct principles. What you want in a work of art is not an exact and truthful resemblance of a group of natural objects, however cleverly arranged and lighted, but a reproduction of such objects, or of a new combination of such objects, according to impressions which they have produced upon the human mind. The first chalk drawings of a schoolboy upon a wall are, in my opinion, more admirable, from the human interest which they possess, than the finest view of inanimate natural objects upon the ground glass of a camera obscura. God created those objects; and He also created man; and man's works are therefore indirectly His works. But man is also the noblest creation of the Deity; and if you follow up this train of thought, you will see that pictures which are the result of human imagination, observation, and *powers of imitation*, are more noble than, and belong to a different class of thing altogether from, the images in a camera obscura, notwithstanding all their beauty of colour and perspective. How much, then, is a work of art more noble than a photograph, with all its imperfections; and what a vast difference there is in principle between a work of art and a camera image! Although I admit the possibility of exhibiting the same artistic skill in arranging objects for the camera as in arranging them for the artist to copy in his own way, yet I maintain that in the photograph of the group there are wanting those qualities which are peculiar to a work of art, and which owe their peculiarity to the fact of the artist's copy *not* being mechanical, but purely the work of human intelligence. The true artist who has mastered the mechanical difficulties of his profession, and takes a high view of its intellectual dignity, will never attempt to build up pictures by photography; in fact, to an accomplished artist, the method would be much too slow, troublesome, and costly, even if the result were not ridiculous. That it is ridiculous is all but self-evident. Can you fancy Tennyson turned photographer, and illustrating his "Lady of Shallot" by a photograph? or Cervantes giving, in the frontispiece of his story of the exploits of Don Quixote, a photograph of a half-drunken model, surrounded with rattletraps and stage property? Are such things possible, I ask? When the Council of this Society, some years ago, banished from the walls of its Exhibition a photograph entitled "The Two Ways of Life," in which degraded females were exhibited in a state of nudity, with all the uncompromising truthfulness of photography, they did quite right, for there was neither art nor decency in such a photograph; and if I expressed a different opinion at the time, I was wrong. There is *no* impropriety in exhibiting such works of art as Etty's "Bathers Surprised by a Swan," or the "Judgment of Paris;" but there is impropriety in allowing the public to see photographs of nude prostitutes, in flesh-and-blood truthfulness and minuteness of detail.

But if artists and poets are not to turn photographers and make such pictures as "The Lady of Shallot" and "Don Quixote in his Study," the artists at least may use photography with advantage in other legitimate ways. An artist who studies largely and conscientiously from nature, acquires in time an originality of style which those who spend most of their life in the studio instead of the field

are fair to copy; and thus arises that plagues of art, "conventionality." The latter class of artists have derived great advantage from photography, because, next to copying from nature, it is good to copy the minute and accurate detail of a photograph in a broad and truthful manner. Artists are fully aware of this, and they have been large purchasers of stereoslides, and it is a common thing for them to cut these slides in half, and exchange duplicates with each other. Thus it happens that slides which have no interest for the public are sometimes largely purchased by artists.

Others, again, like Mr. Frith, use photography largely in obtaining studies for parts of their pictures. Thus, on "A Derby Day," Mr. Frith employed his kind friend Mr. Howlett to photograph for him from the roof of a cab as many queer groups of figures as he could; and in this way the painter of that celebrated picture, the "Derby Day," got many useful studies, not to introduce literally into his picture as Robinson or Rejlander would have done, but to work up in his own mind and then reproduce with the true stamp of genius upon them.

Artists may, and do, in this way use photography largely and profitably; but the tyro in art should never forget that one great secret of success in his profession depends upon his acquiring the power of closely observing the form, colour, and expression of objects, and recording them in his memory. It would not do for Leech or Tenniel to be dependent upon a camera for recording all the funny incidents they may see in London streets. An artist may use a camera occasionally as a help, but he must not trust too much to it.

I will now point out a new use which may be made of photography by persons (like Dr. Livingstone, say) who may wish to illustrate a book of travels with truthful pictures, based upon photographs, but pulled in the printing-press. All that is required to do these things artistically is to practise pen-and-ink drawing until facility is acquired in that art. I have myself made one or two attempts, and with sufficient success to confirm me in my belief that the art is not difficult. The plan is as follows:—

You first take a negative and print a positive from it, in the usual way, or, if you like, without gold toning. The photograph need not be faultless; and a few stains, spots, and comets do not signify, provided the general outline of the objects is preserved. You then lay upon the positive print a sheet of lithographic tracing-paper upon which transfers are made. This costs about eighteen-pence per sheet, demy. Then, either with a quill pen or a fine steel Perryan pen dipped in lithographic transfer ink, you make a pen-and-ink drawing upon the tracing-paper, guided by the photograph beneath. In doing this be careful not to rub the tracing-paper with damp fingers, or let any grease or dirt get upon it. The transfer ink is sold in solid cakes, having a rather agreeable smell, and is rubbed up with water in the same way as Indian ink. In making the sketch, observe that gradation of tint is got, not by using thinner ink, but by drawing your lines nearer together or further apart. In parts of the picture where broad masses of intense black occur, these may be laid on with a brush, but very carefully. Before commencing this art of pen-and-ink drawing, study carefully some good etchings or wood engravings. The amount of finish required will depend, of course, upon the nature of the subject. It is better to aim at producing a broad and suggestive effect, with the minimum of work, than to get into a small, laborious and niggling style. All the masses or systems of lines by which the various shades are produced must be drawn in a suitable direction, and with a masterly touch evincing forethought in the artist. When the sketch has thus been made, you immediately send it to a lithographic printer, and he in a few minutes transfers it to zinc or stone; and from this impression any number of prints can quickly be pulled for the purpose of book-illustration. You must not think it heretical in me to say so; but I generally like these sketches better than the photographs from which they were taken, however perfect the latter may be. There is a firmness and crispness about an etching or pen-and-ink sketch which photographs do not possess, to say nothing of their pretensions to a fine-art character when properly done. There is a great advantage also in being able to utilize bad photographs, or rather in being a little independent of the messes into which photographers sometimes get.

Now that rapid dry plates are coming into fashion, artists will find it a great help to them to use these plates with a reflecting camera, for taking groups of figures, animals, &c. I have sent Mr. Ross a plan of an artist's reflecting camera, constructed expressly for this purpose; and I am sure that an instrument

of this sort, with rapid dry plates, would be of great value to artists. In fact, photography ought now to be made a part of the course of instruction of every artist.

The magnificent series of photographs lately published by Messrs. Cundall and Downes, of the pictures in Turner's "Liber Studiorum," prove convincingly the great use of photography for reproductions of this kind. Mr. Bingham's admirable photographic copies of paintings seem also to leave nothing to desire. Should it be said that photography fails somewhat in the truthful rendering of colour by shade, yet, on the other hand, you are certain of preserving expression, which is a matter of greater consequence. Who would not rather have a fine photograph by Bingham, of Guido's celebrated picture of "Beatrice Cenci," the expression of which has been found so difficult to render faithfully by engraving, than a print of the same?

Photo-lithography is another very useful application of photography; and wonderful reproductions of maps and line drawings have been made by its means, in the hands of Sir Henry James, Mr. Osborne, and Mr. Ramage. The attempts which have been made to print by this process from ordinary negatives, by Macpherson, Poitevin, Lemerrier, and others, have been less successful; but I really must say that Mr. Pouncy, of Dorchester, has got a step in advance, and done some good things. Take, for instance, his view of Killarney, published in my "Notes;" that is surely excellent. My impression of this process is, that it is suitable only for a certain class of subjects, of which Killarney is a good illustration, and that the fault has hitherto been in attempting to apply it to the wrong kind of subjects. The subjects for which photo-lithography is suitable, are precisely those for which lithography is commonly employed, and of which Mr. J. D. Harding's lithographs are the type. If photo-lithography can produce works of this class, without the conventional mannerism which many artists acquire, they will be very useful to artists and drawing-masters. But it must be remembered that the grain of a lithograph is one of its characteristic features; and photo-lithographs must always, from the very nature of the case, have a grain. In this respect they must always differ from common photographs. A lithographic printer will always tell you of the importance of "keeping the work open;" for as soon as the grain becomes blocked up there is an end of half-tone, and the proofs exhibit dense patches of black. Bold bits of detail are the kind of thing for photo-lithography; and these bits will only be found by a man who thoroughly understands what is required, and has a great deal of taste and artistic feeling. They may be taken upon paper, and with this advantage, that the negative can be reversed in the printing-frame, if necessary. The fine detail of a glass negative is not required. Jersey abounds in studies for the photo-lithographer, although it is rather a bad place for general views.

There are two processes of photo-lithography—one in which the stone is coated with a solution of asphaltum in ether, benzole, or turpentine; and the other, in which it is coated with a mixture of bichromate of potash and gelatine. The former process is that of Mr. Macpherson, and I believe also of Mr. Pouncy; the latter of M. Poitevin and Sir Henry James. It is impossible for me to say which is the better; but the former not only allows you to grain the stone, but also the sensitive coating of asphaltum, before exposing it under the negative. While on the subject of asphaltum, I may mention the possibility of taking permanent prints upon paper with this substance, with all the fine qualities of a silver print, except its beauty of colour. The asphaltum prints have a very disagreeable yellowish-brown tint; and their only recommendation is their permanency, about which very little doubt can exist. For some subjects, however, the colour is not unsuitable.

The phototype process of M. Joubert is very nearly all that one could desire for good carbon printing upon paper. It is a great pity that photographers do not club together and buy it. The sum required by M. Joubert has never been publicly named; but he has confided to me the amount for which he would dispose of it, when I was in treaty with him, a year ago, to buy it for my own use, and I thought the amount reasonable, although more than I felt justified in giving on my own responsibility. If the required sum could be subscribed quietly, and in a way not unpleasant to M. Joubert, it would be money well laid out. If I could be of any use in privately furthering a scheme of this kind, I should be most happy.

Very little appears yet to have been done in the application of photography to scientific purposes, chiefly, I think, because

the collodion processes are employed instead of the daguerrotype. A great deal has been said about Mr. De La Rue's experiments in celestial photography; but I really cannot see that they have proved anything. Take, for instance, his stereo slides of the moon: those merely illustrate the fact of the roundness of the visible part of the moon, which was known before, and they do not prove that the mountains stand out in actual relief, as some people suppose they do. If a smooth globe were painted with dark patches, and stereo views of it were then taken from different stations, these duplicate views would make the painted patches appear in relief, and that relief might easily be mistaken for the kind of relief due to unevenness of the surface of the sphere. Sir John Herschel has had something to say on this subject lately in the *Cornhill Magazine*, but he does not attach undue importance to Mr. De La Rue's slides, or make it appear that they have proved anything new. The photography, in Kew Observatory, of the solar spots has not yet amounted to much; and it will be found, I am sure, before long, that a better instrument and better process are necessary to produce valuable results.

I have now, gentlemen, endeavoured briefly to call your attention to some of the uses and abuses of photography, in hopes that my remarks may lead to a profitable and animated discussion. I have mentioned in my paper the names of Robinson Rejlander, and De La Rue; but it must be distinctly understood that I meant no disrespect to these gentlemen; on the contrary, I consider them very talented in the particular way in which they excel. Mr. De La Rue is a gentleman who undoubtedly stands high in science; and Messrs. Robinson and Rejlander are not less distinguished in legitimate photography.

I have enclosed a few sheets of my patent albumenized paper for distribution among the members, and also a print upon it taken from a panoramic negative. You will observe in this print the perfect purity of the whites, and the extraordinary vigour of the blacks, without any bronzing. There are also a sheet of blotting-paper and a sheet of plate-paper, one half of each of which has been dipped in the india-rubber solution, and the other half not. You will see that you can write upon the half which has been treated with india-rubber as well as upon common paper, but not, of course, upon the other half. This proves the effect of the rubber solution as a sizing material; and if the ink does not sink into blotting-paper when treated with it, it will easily be understood that the albumen will not sink into photographic paper when so treated. I have also enclosed a sheet of Rive paper prepared with the rubber solution, so that you can see it before it is albumenized. You will observe that there are no visible traces of the india-rubber either upon the Rive paper or the blotting-paper, and that it does not stain the paper, or visibly affect it in any way; neither is there much smell.

I have great hopes that prints upon the patent paper will be found more permanent than those upon common paper, on account of their absorbing moisture less readily. I have immersed finished prints in the rubber-solution, and this, I think, will afford great protection to them. The treatment does not in any way affect the purity of the whites, and it seems to make the surface shine still more. I think it very desirable that valuable card portraits should be treated in this way.

If any of the members of your Society would like to send me some of their negatives, I will, with pleasure, send a print from each, upon the patent paper, for your Society's Album or for exhibition at a meeting. I am very anxious to get some good negatives to print specimens from, in order in the spring to have an exhibition of positive prints at Mr. Lamprey's warehouse, in Paternoster Row, and to be able to send round to the different Photographic Societies a portfolio of fine and varied specimens.

THE APPLICATION OF PHOTOGRAPHY TO THE MAGIC LANTERN EDUCATIONALLY CONSIDERED.

BY SAMUEL HIGHLEY, F.G.S., F.C.S., &c.*

AS TO THE PRODUCTION OF THE POSITIVES, OR TRANSPARENTS OF GLASS.—Following the system of the Microscopic Society, we ought to adopt a standard gauge for our glasses, say three-and-a-half inches square for views for the general run of lanterns. The process—old structureless collodion,

exposure in diffused light—the nearer it can be brought to a standard character the better. Iron development, after intensification with pyrogallie acid by Major Russell's process; fix with cyanide of potassium, varnish the picture to give transparency to the film, mount between two glasses; or the albumen process may be followed with advantage, especially for "superposition printing."

Where, however, lantern views are to be prepared for trade purposes, it is better to produce them by "camera printing," from negatives of large size, for by this method the producer is enabled to supply views, larger or smaller than the standard size suggested, according to the special requirements of his customers, and greater definition or sharpness is likewise attainable. I have stated that the nearer we can bring the light employed for printing transparent positives to a standard character the better, for the operator would then attain to uniform results, and loss through failures would be greatly diminished. It is also desirable that the operator should be made independent of the sun's light, for after two seasons' experience I find that when the stock of views one has prepared during the summer months is carried off, at the time of demand, the winter months, through failing light, it is difficult, at times impossible, to meet the requirements of would-be customers. To avoid this annoyance I have lately given my attention to the production of an artificial light, rich in actinic or photogenic rays, cheap in production, and that could be turned on or off as required, with what promise of success I will presently demonstrate.

It is true that we could use carbon points, or a fine stream of mercury, brought to a state of intense ignition by means of the electricity produced by forty Groves's cells, but both the ordinary electric light, and Way's mercurial electric light, are too costly in the "plant" to be economically considered. It is commonly believed, and frequently stated in some of the photographic journals, that the oxy-hydrogen light may be employed for photographic purposes, but the fact is, and I wish it to be distinctly understood, that though very brilliant and intense, it is peculiarly wanting in actinic rays. Some time since, my friend, Mr. Charles Heiseh, was preparing a lecture on photography, and wishing to give an illustration of the method of producing a picture, he thought he should be able to demonstrate the point by aid of the oxy-hydrogen light, but he found, experimentally, that while he could produce a sharp picture of a white bust, instantaneously, by the electric light, he could only produce a dingy image of the same object after twenty minutes' exposure to the oxy-hydrogen light. It is well known that if an artificial light emits fluorescent rays (known by their peculiar effect on bodies possessed of the character called by physicists "fluorescence"), that light is also rich in actinic or photogenic rays. I shall now show how far the light I have been experimenting on is likely to be of utility to photographers. [Mr. Highley here turned on from a gas-jet a bright violet sheet of flame that made an uranium glass, brought into its presence, glow like a gem.]

The cost of production is always a legitimate subject of discussion, and I may, therefore, state that, taking into consideration the cost of production of negatives (our engraved plates, so to speak), the cost of making the existence of the subject known, in other words, the advertising charges, and the cost of producing the transparencies, photographic magic lantern views can be sold to the public for five shillings each, plain, and eight shillings and sixpence coloured, while the ordinary magic lantern pictures, which, as I have previously stated, cannot for one moment pretend to embody the same amount of detail or truthfulness to nature, sell at just double that price, that is to say, sixteen shillings coloured, if of the same size and pretensions to artistic excellence. On the other hand, it should be stated that photographs involve a slight extra expense in the apparatus required, for an oxy-calcium or oxy-hydrogen light, and achromatic lenses are essential for their perfect exhibition.

As ordinary magic-lantern pictures are in the main made up of patches of colour, they can be shown by lenses that do not require great optical perfection; as, however, photographs are made up of detail, if they are shown with lenses that are not achromatic, a fringe of colour will be apparent on every line, and this defect in the optical parts of the apparatus used in their exhibition, will tend to produce a blurred effect, in fact a picture wanting in definition.

But photographic magic-lantern views, even when not in use, may be made available for educational purposes; for I would

* Continued from p. 44.

suggest, that, if they represent Natural History subjects, instead of stowing them away in boxes, they should be placed in the open cases of museums, &c., beside allied objects, care being taken that they are fixed at such an angle that light should be reflected through them, by aid of a piece of white paper placed behind the transparency—or by mounting the views in long frames backed with fine ground glass, they might serve as appropriate borders to the windows of a scientific institution.

To make our system perfect, it behoves the producer of photographic lantern views to consult the requirements of the curator or travelling lecturer, and make the demonstrating apparatus as compact and generally useful as possible. I have therefore given thought to these important points, and now beg to call your attention to some of the contrivances I have introduced.

The sources of light may be the electric lamp, which, from its intensity, is well suited for institutions or large lecture theatres; yet for ordinary use it is too expensive, as it cannot be worked to advantage with less than forty of Groves's cells, and these, with a lamp, cost not less than thirty pounds (without a lantern). Some lamps, such as Serrin's, cost, *per se*, twenty pounds, but at the International Exhibition I exhibited a novel form of automatic electric lamp, founded on a galvanometer arrangement, the invention of Dr. Squire, which, when perfected, will be quite as efficient as those of our French neighbours, Dubosq and Serrin, and cheaper through there being a simplification of parts. A model of this lamp is on the table.

For general purposes, the oxy-hydrogen light is most efficient, and as the pure hydrogen formerly employed is now usually replaced by ordinary house gas, the trouble is greatly diminished. Undoubtedly pure hydrogen gives a better light than the carburetted form, and when house gas is not attainable it may be best produced from a leaden generator, constructed on the principle of Doebereiner's lamp. The vessel being divided into two compartments, the lower part is filled with sulphuric acid and water till it runs out at the tap; the tap is then closed, and the acid mixture acting upon a cylinder of zinc supported on the outside of a tube connecting the upper with the lower chamber, causes hydrogen to be generated, which, having no vent, forces the liquid up the tube into the upper chamber; as soon as the acid is removed from contact with the zinc, the production of gas ceases. On the tap being turned, the liquid descends and forces out the hydrogen with considerable pressure. The acid, on rising within the lower chamber, again comes in contact with the zinc, and again causes the gas to be generated, and thus, if the apparatus is properly constructed, the hydrogen is supplied under pressure and as fast as it is consumed (Fig. 3).

Fig. 3.

The hydrogen may also be generated in a glass Woulfe's bottle, and be stored in a gasometer, or gas bag, till wanted, or common house gas may be passed into either of these re-

ceptacles, and expelled under any given pressure by means of weights.

Oxygen gas is readily and safely prepared by placing a mixture of two parts of small crystals of chlorate of potash to one part coarsely ground oxide of manganese, into a conical copper retort, which is then closed with a cap or safety valve of vulcanised india-rubber tubing, and connected with the long tube of a wash bottle, for the purpose of freeing the gas from dusty particles or other impurities. The heat of a lamp is then applied, and as soon as the oxygen begins to issue from the short tube of the wash bottle, it is connected by a flexible tube with a wedge-shaped gas bag, as shown in Fig. 4, and so collected and stowed for use.

Fig. 4.

(To be continued.)

Proceedings of Societies.

LONDON PHOTOGRAPHIC SOCIETY.

THE annual meeting was held at King's College on the evening of Tuesday Feb. 3, the LORD CHIEF BARON in the chair.

The minutes of the previous meeting having been read and confirmed, the Viscountess Hawarden and the following gentlemen were elected members of the society:—Messrs. J. L. Wensall, A. Sylvester and W. Austen.

Some pleasing specimens of photography on opal glass were exhibited by Mr. Portbury.

The CHAIRMAN announced, that as no new nominations had taken place at the last meeting, the gentlemen proposed by the council, at the meeting in December, would, in accordance with the rules of the society, become officers for the ensuing year.

The names of the officers for election or re-election would stand as follows:—The Lord Chief Baron as President, Mr. Glaisher as Vice-President, Mr. P. Le Neve Foster retiring from that position into the council; as members of council, Messrs. Henry Pollock, J. Cole, Hennah, Lieut.-Col. Stuart Wortley, and Lord Henry Lennox.

The SECRETARY then read the auditors' report, which congratulated the society upon a more favorable state of the funds than had existed for some years, the excess of income over expenditure being, £32 18s. 0d. The number of new members during the year had been thirty nine, against sixteen during the previous year.

The SECRETARY then read a letter from Mr. Fenton, announcing the award of prizes in the exhibition of the society, with the reasons for the decision at which the adjudicators had arrived. We shall publish this report in our next.

Lieut.-Col. STUART WORTLEY then read an interesting paper on the production of instantaneous pictures of large size, which will appear in our next. After the thanks of the meeting had been given to Col. Stuart Wortley,

The SECRETARY read a letter from Mr. England, describing a method of testing coloured glass for use in the dark room, accompanied with illustrations of the suggestion, consisting of a series of pieces of yellow glass, about two inches square, of different tints. These were arranged side by side between two white glasses, and each piece numbered. A piece of sensitive paper was then exposed for some hours under these glasses, and their respective powers of resisting actinic rays thus ascertained.

Mr. P. LE NEVE FOSTER asked Col. Stuart Wortley what especial benefit he found from the use of the iodide and bromide of lithium.

Col. STUART WORTLEY said it dissolved very freely in alcohol, yielded a clean and good picture immediately after the collodion was mixed, and gave fluidity to the collodion, which rendered it valuable for use with large plates. The collodion was moreover very sensitive and stable, not changing within ten months, which was the longest time he had kept it.

Mr. VERNON HEATH, expressed a conviction that the great future of photography largely depended upon the production of instantaneous pictures, and the subject was therefore peculiarly interesting. He wished, therefore, to ask Col. Stuart Wortley whether he had taken any instantaneous pictures in this country, or only in the light of Italy. He should also like to know what means were used to secure instantaneous exposure. Every one who had seen the beautiful pictures in the exhibition, must be very anxious to obtain any information which might enable them to take such pictures in this country. He would also add, that he had listened with great interest and pleasure to the remarks in the paper on printing. He was convinced that no one could so fully understand the qualities of a negative and the results it ought to yield, as the photographer who had produced it; the mere printer, unfamiliar with the scene, and the effect which would best render its character, could not produce the prints best for the purpose; and he thought it would be doing a great deal of good to urge the importance of every photographer printing his own negatives.

Colonel STUART WORTLEY had not practised instantaneous photography in this country; but, from some recent experiments in portraiture, he was led to believe that there was not that difference in the light of Italy and this country which was imagined. In some respects the advantage, so far as landscape photography was concerned, was found in this country. It was very difficult to render distance in Italy, on account of the hot vapour which generally hung over the horizon. The only time when it was possible to succeed satisfactorily was the day following a thunder storm or rain.

The Honourable W. VERNON had found that early in the morning was the best time for landscape photography in Italy. He wished also to add his conviction in confirmation of the remarks of Colonel Stuart Wortley and Mr. Heath as to printing.

Colonel STUART WORTLEY said, regarding his method of exposure, he simply used his hand. It would be noticed that his pictures were fully exposed; indeed, the process was more rapid than the exposure, sometimes a little blurring of moving objects being observed. He wished he had a more rapid method.

Mr. J. W. OSBORNE wished to ask three questions. Colonel Stuart Wortley had referred to a liberal use of acetic acid in conjunction with formic. How much constituted a liberal amount? Second, he asked his reason for using bichloride and iodide prior to the use of pyrogallic acid and silver. He had himself adopted that plan when he found it difficult to get sufficient intensity, but he wished to know what was the object of using it generally, when the opposite method, that of using pyro and silver first and bichloride afterwards, was so much more usual. Third, he wished to know why Dallmeyer's triple lens was used, seeing that an impression prevailed in some quarters that it was slower than the single lens, owing to the number of reflecting surfaces. Was it because of its known freedom from distortion, or because it permitted the use of the full aperture, and thus practically quicker than others, or for some other reason?

Col. STUART WORTLEY used as a rule as much acetic acid as formic acid, but varied according to the temperature and the light, trying a plate in the morning to ascertain. If there were not sufficient acetic acid, the picture flashed out too quickly for control, and about two inches of the plate, where the developer first came in contact, was fogged. By adding more acetic acid the image was a few seconds before it appeared, and then developed satisfactorily. The formic acid aided in giving

amazing detail. Mr. Simpson would remember a specimen he sent over from Naples to him, which especially showed this quality.

Mr. G. WHARTON SIMPSON said the picture in question was one of the most exquisitely detailed pictures he had seen, and of a difficult subject.

Col. STUART WORTLEY said as he intensified his negatives after they were dry, some of them having been taken in Italy and intensified in this country, he found a method of producing an iodide on the surface of the picture prior to the application of pyrogallic acid and silver was desirable, otherwise the negative would not intensify easily.

A conversational discussion on this subject followed, in which Dr. Diamond remarked that he had seen Col. Wortley's manipulations, and whilst the pyro and silver applied to a dried plate would not take at all, nor give intensity, after the application of bichloride and iodide no difficulty was felt.

Col. STUART WORTLEY said, in regard to the question about the lens, he used the triple lens because it covered a larger sized plate more perfectly than other lenses of the same focus which he had tried. He was sorry he had not some of the pictures at the meeting to show, but they were all at the exhibition.

Mr. OSBORNE: Do you think it the best lens?

Col. STUART WORTLEY: I have not found any so good; but I have not tried everybody's lenses. Without wishing to depreciate others, I think it right to state which I have found answered best.

Mr. HEISCH said he had recently intensified six dozen negatives taken in the Holy Land, and had used nothing but pyro and silver. He had found no difficulty in producing intensity.

Col. STUART WORTLEY asked if they were developed with iron.

Mr. HEISCH was uncertain.

Mr. DEBENHAM was in the habit of intensifying with pyro and silver without difficulty. The negatives were developed with iron, using bromo-iodized collodion.

Col. STUART WORTLEY said much would depend upon the amount of deposit to begin with.

Mr. SEBASTIAN DAVIS referred to some experiments he had made with single and compound lenses. Using a stereoscopic single lens and one of Dallmeyer's double lenses of similar focus he found that with an aperture of $\frac{3}{8}$ ths of an inch in the single lens, and $\frac{1}{4}$ ths of an inch in the double lens similar results as regards definition and intensity were obtained. In the exposure the single lens required 10 seconds, whilst the double lens required only 4 seconds. The double lens was the most rapid in the ratio of 4 to 10. Regarding the triple lens, it doubtless gave fine results, but he did not think satisfactory definition all over the plate was obtained with the full aperture; a somewhat small stop being required to secure good marginal definition. In many of Col. Stuart Wortley's pictures the margin was removed by vignetting, so that any defective definition was not seen. On the whole, he was disposed to think that a single lens was more rapid.

Col. STUART WORTLEY assured Mr. Davis that the vignetting was not due to any defect of the lens, but solely for the purpose of producing an artistic picture. Besides, some of the pictures were not vignettted, and he thought that it would be seen in them that the whole plate was well covered. He ought to mention also that the lenses used were only intended for plates 6 by 5, and 8 $\frac{1}{2}$ by 6 $\frac{1}{2}$, whilst his pictures were very much larger.

A communication from Dr. Van Monckhoven on the Theory of Photographic Processes, was then read by Mr. Shadbolt, but elicited no discussion.

The CHAIRMAN proceeded to make some interesting remarks on the practical progress of photography, but confessed that he had been somewhat disappointed that more light had not been thrown on its scientific and theoretical aspects. He thanked the society for the honour they had done him in his re-election. His years forbade the hope that he could much longer till such an office, and hoped the society would not neglect an opportunity of securing more efficient services; adding, however, whilst they might find a more able chairman, one more willing and zealous for the interest of the society they could not possibly have.

The Secretary announced that at the meeting in March Mr. Johnstone, of Birmingham, would read a paper on the Electric Theory of Photography. After some votes of thanks the proceedings terminated.

Correspondence.

NATURE AND CONSTITUTION OF THE FINISHED NEGATIVE.

DEAR SIR,—Permit me to make a few observations in the NEWS upon the discussion of an important topic, respecting which much has been said and written of late, namely, "The Nature and Composition of the Photographic Image." I think the statement of the problem to be solved embodied in this phrase is somewhat vague, and has conducted, in some measure, to give vagueness to what we have read upon the subject in your own and other journals.

Some persons evidently think it necessary to explain the *modus operandi* of the subtle chemical and molecular changes produced by the actinic rays. These they illustrate by divers similes, designed to convey the idea of unstable equilibrium, and pass on naturally to the mode in which the developer acts, thereby involving themselves in the mazes of two most difficult questions, respecting which very little is known, or will be, until inductive reasoning, based upon cleverly devised experiments, and the closest observation, is brought to bear upon them. Now, if photographers confined themselves to the investigation of the dark deposit in the collodion film, or rather made that a separate subject for the present, perhaps some progress might be made; for I quite agree with Mr. Malone, that enough time has been spent on conjectural statements, and what we want now is facts. It appears to me that the determination of the nature of the substance which produces the opacity in a negative is quite within our reach; but it will never be arrived at by speculation alone, which is legitimate only so far as it guides our experiments. I am not about to enter upon this subject in the present communication; but I wish to bring under the notice of such of your readers as occupy themselves with its investigation, a fact which should not be overlooked.

If, after fixing and drying any ordinary negative, but especially one of a black and white subject, such as an engraving, the surface of the collodion film be carefully examined, the transparent parts of the picture will be found to be relatively depressed in a very striking manner. I have been aware of this fact for a long time, and have speculated much upon its probable cause, and the uses which might be made of it, and have also written respecting it long ago to Mr. Hadwich, requesting him to bring it before the Society; but when he received my letter, he had already left King's College. I have never seen a statement of this phenomenon in print, nor any allusion to it; but the idea that it had not been observed before was instantly dispelled by yourself and Dr. Diamond, on my arrival in England in July last. Being therefore known, I certainly am surprised that it has not been put prominently forward as an important item in the consideration of the deposit in the collodion film; for I do not think that any one of the talented men, who have thought and written on this subject, will venture to maintain that it is the actual bulk of the metallic matter in the collodion, which gives rise to the differences in elevation of the transparent and opaque places, a difference by no means so slight as might be supposed.

A copy by mechanical means may be taken of the depressions in any negative, in the copperplate printer's press, or even in one used for lithography, if a sheet of tin foil in contact with its surface be submitted to the necessary pressure. For this purpose, the soft, spurious description of tin foil, largely alloyed with lead, is the best fitted, and some experience and care is desirable if the negative is a valuable one. But I have succeeded in producing from negatives of a variety of kinds many excellent copies on metallic surfaces, in the way I have described, and by other means less satisfactory. Copies of this kind serve to establish incontestably the reality of the depression, which some persons detect with difficulty upon the glass; and to

show that its amount entitles it to serious consideration, I purpose exhibiting a few specimens produced by my method at an early meeting of the Society.

We have frequently been told that one of the advantages collodion offers for photographic work arises from its absolute indiffidence, chemically speaking, to the silver salts. This may be so. I do not now intend to controvert it; but the fact above cited seems to me to make it appear probable that a change of some kind has taken place in the collodion itself, where the light has fallen, and that its condition in such places is not the same as it is in the shadows.

Until lately most of us were under the impression that the white parts of a positive print contained no silver. We took for granted the power of the hypo to break up any uncoloured combinations between silver or its salts, and albumen. Our opinions are now modified, and I draw the obvious moral from the change, and applying it to statements made respecting collodion, object to take its total indiffidence for granted, while I am far from regarding its chemical activity as proved. I am, dear Sir, yours truly,

J. W. OSBORNE.

61, Beaumont Street, Portland Place, W.
January 26, 1863.

Photographic Notes and Queries.

RESIZED PAPER.

DEAR SIR,—Further experience with this paper has led me to the conclusion that a floating of three minutes on the sensitizing bath, if of 80 grains strength, is amply sufficient to give, not only a good, but a brilliant picture. Apologizing for troubling you, I am, dear sir, yours truly,

W. H. WARNER.

Ross, January 16th, 1863.

PHOTOGRAPHIC PIRACY.

SIR,—It has occurred to me that the infringement of copyright in photographs might be prevented by making the sale of photographs, not bearing the name and address of the photographer, an illegal act on the part of the vendor, punishable by fine for each separate sale. If the vendor were thus responsible, he would not venture to sell pirated copies. The actual copier should be liable to a much heavier fine. To "counterfeit" the name of the photographer would of itself be forgery.

I am not aware how far the law, as it exists, may be effectual for this purpose; but, as the evil is so notorious and extensive, I should think there is good ground for getting, if necessary, some such power over the vendor, when the general subject of copyright is reconsidered, as it probably will be, this session.—I am, sir, your obedient servant,

ALEXANDER BASSANO.

February 3rd, 1863.

[We fear it would be difficult to obtain the power our correspondent suggests. We hope that the law as it stands, if vigorously applied, will be found efficient in suppressing the disgraceful piracy which has hitherto been as a cankerworm injuring the art.—ED.]

LEUT.—Light also has an undoubted influence on the growth of some of the lower animals. Animalculæ grow, in water, much more readily in the light than in the dark. If equal numbers of silkworms be exposed in a light room and a dark, many more larvæ will be hatched from the former than the latter. And, what is stranger still, Dr. Edwards found the development of tadpoles into frogs may be entirely prevented by the absence of light. They grow into big tadpoles. Several facts tend to the belief that the human body is greatly amenable to the influence of light. Dr. Edwards found that persons living in caves or cellars, or in dark streets, are apt to produce deformed children; and the workers in mines are liable to disease and deformity beyond what could be accounted for by the condition of the atmosphere. And it has even been affirmed by Sir A. Wylie that in a large barrack at St. Petersburg the cases of disease in those men who live on the dark side for many years are three to one to those on the light side.

Talk in the Studio.

ART PHOTOGRAPHY.—At the next meeting of the South London Society, to be held in the City of London College, Leadenhall Street, next Thursday evening, Mr. Rejlander will read a paper, entitled Rejlander's Apology for Art Photography. Mr. Price, also, will read a paper on the Theoretical Principles of Positive Printing.

PHOTOGRAPHIC COPYRIGHT.—Mr. Sothorn having become a world-wide celebrity, the world naturally desired to have his portrait; and so he consented to sit to Mr. Hering, the eminent photographer of Regent-street, for no less than nine *cartes de visite* representing him in so many highly diverting and Dundrearyish attitudes. These productions, most elaborately and artistically executed, have had, it appears, a prodigious sale. It seems to have occurred to a person named Daniells, a photographer carrying on business in Pentonville, that a very good speculation might be made out of the Dundreary mania, by counterfeiting, or forging, or re-photographing Mr. Hering's pictures, the copyright of which had been duly secured, and notices to that effect affixed to the front and back of each likeness. This disgraceful simulation was ere long discovered. Daniells appears to have sold numbers of the spurious *cartes de visite* at a very low rate; but his tricky trade was brought to a sudden stand-still by a couple of summonses to appear at the Clerkenwell Police Court, there to answer for a wilful and wanton violation of the 26th and 27th Victoria, which punishes the infringement of artistic or photographic copyright in copying or selling any such work of art, without the consent of the proprietor, by a forfeit to him of a sum not exceeding ten pounds and which also provides that all existing copies, repetitions, and imitations, and the negatives from which the photographs have been printed, shall be confiscated. Nothing could be clearer than the evidence which brought home to Daniells the offence of having made use of the original Dundreary for his own counterfeits. The only question was a technical one respecting the Artistic Copyright Act, which requires to be affirmed by some high judicial decision. With a view of fixing the meaning of the law, the sitting magistrate, Mr. Barker, inflicted a penalty of three pounds and sixpence, together with two guineas costs, in order that the defendant might appeal if he so chose. Such a course he has elected to pursue; but if he be wise in his generation he will desist from disputing the decision arrived at. Recent experiences and common sense convincingly prove that there should be as clearly defined and as rigidly enforced a copyright in an original photograph as in an original picture; and if the law we already possess is loosely or vaguely worded, it must be speedily and precisely amended.—*Telegraph.*

To Correspondents.

** WE must again crave the indulgence of a large number of our advertising friends whose announcements are compelled to stand over until next week.

M. W.—Very little is written on the Calotype process at the present day, simply because it is little practised. Dr. Diamond is one of the best Calotype manipulators we know, and you cannot do better than follow the instructions in his article. Those, or the instructions by "Theta" in our own pages, will aid you to produce satisfactory results.

D. A.—We are glad you find the gold and lime bath so successful. We have not used the lens to which you refer, but have heard it well spoken of, and have seen some good work done by it.

SPECLUM.—The film splitting and curling off the plate may be due to several causes, but the condition of the collodion is most frequently the primary cause. Some kinds of pyroxyline have an especial tendency to this defect, and weak solvents, containing too much water, materially tend in the same direction. Dirty plates or damp plates will also cause it. When the tendency is found to exist, be very careful that the plate is clean and quite dry; see that the film is well set before immersion; be very careful to avoid under-exposure, as under-exposure and prolonged development will bring it about if the slightest tendency exist from other causes. When this result is feared with a good negative, pour a solution of gum or albumen on the film before it dries, and varnish afterwards as usual.

G. F. P.—See answer to "Speculum." For your printing bath, agitate it with kaolin, and filter.

MADDER BROWN.—You may of course obtain good photographs by purchasing published pictures, but as this would be a somewhat expensive mode of getting prints merely to practise colouring upon, you will doubtless be able to procure some on moderate terms by applying to any professional photographer, who generally possesses spare prints.

EXCELSIOR.—The system of prize-giving generally stimulates exertion; but we fear that in connection with the Exchange Club it would involve some

difficulties, and would certainly increase the responsibility and already invidious duties of the referees. Your letter shall, however, be handed to them for consideration. The date and hour of exposure should always be appended, as well as the time, lens, stop, and other particulars.

A. BEGINNER.—The most common cause of a sandy surface is supersaturation of the bath with iodo-nitrate of silver. See an article on page 597 of our sixth volume, the number for December 12, 1862, and on page 590 in the same number. A bath which has been boiled down will be very likely to give it. To remove the cause, dilute the bath with an equal bulk of distilled water, let the solution get as cold as you conveniently can, and then filter. The hurning of gas is not desirable in a dark room, but it is not likely to cause the sandiness referred to.

M. M. D.—A square inch of coloured glass is sufficient for our examination. We do not require any fee for the examination, but have pleasure in undertaking it for our readers. 2. Doubtless you can purchase a good iron negative of almost any professional photographer. If you do not know any, we can furnish you with the names of some.

AMARANTH.—The lens you have procured is probably the best you could possess for your purpose. 2. It is not so quick as a portrait lens; but as quick, or quicker than other landscape lenses. 3. We prefer an iron developer for all purposes. We shall always have pleasure in helping you by our advice.

G. H. MARTIN.—The card sent is very round and brilliant. The printing is especially fine, and the tone good.

J. W. P.—The letter was posted with the proper address added. **QUERCUS.**—Printing by development has not generally been successful with albumenized paper, but it can be done. The albumen must, in such case, contain a bromide, or bromide and iodide, as well as a chloride. The process will then be similar to that on plain paper. 2. The copies to which you refer are very diminutive, a bust about the size of a shilling mounted on the ordinary sized card. A number of prints are probably copied at once, forming one large negative. The results are very poor; but, taking everything into consideration, we should not like to produce them at the price.

W. WARRINGTON.—The size of the condenser commonly used in the solar camera is nine inches, and the focus eighteen inches.

A THREE MONTHS SUBSCRIBER TO THE NEWS.—For a first attempt your prints are promising. They all require printing deeper, and all the negatives have a little too much top light, which causes heavy shadows under projecting features. Cover more of the skylight immediately over head, and get a little shadow on one side of the face. No. 1, the face is flat from over-development or over-intensifying. No. 2 is better in this respect, as also is No. 3. No. 4 is flat in the face from too much light all round it, and a little over-intensifying. With care and perseverance you will succeed. Let us hear of your progress.

A PRINTER'S ASSISTANT.—You have used too large a proportion of alcohol and too much silver. Nitrate of silver is very sparingly soluble in alcohol, and when you add one-third of its entire bulk of alcohol to an 80 or 100-grain solution, the probability is that the alcohol will float on the denser fluid, and even if well stirred up, they would not mix without precipitating some of the silver, and hence the mottled effect of your prints. As a remedy, add an equal quantity of a new 60-grain solution. 2. Filtering water only removes matter in suspension; it does not get rid of chlorides, carbonates, &c., and therefore does not form a substitute for distilled water where the latter is imperatively required. 3. Soap and water should not be used for washing prints, the soap is useless and injurious. 4. We have not used magnesia in a toning bath. It might be used, but we don't know of any special advantage in its use. 5. About a quarter of an hour is the time required for fixing. If the paper be thick, the bath weak, or the weather cold, a little longer may be an advantage. 6. We use methylated spirit for almost every photographic purpose, instead of pure spirit without disadvantage. 7. Intense negatives and deep printing are requisite in order to ensure purple or black tones. The acetate of soda bath will give fine purple tones, but the lime bath gives black tones most readily.

GEORGE GUYEN.—We regret to state that the Almanac is out of print. We printed of this year's issue a very large number in excess of what had been done before, being warned by the experience of last year, at least 500 applications having been made after the work was out of print. Our calculations have, however, been at fault, the demand having again exceeded them.

ALPHA.—Two quarter-plate portrait lenses may be used with advantage for the production of stereoscopic pictures. 2. A fallacy used to prevail to the effect that so much as a passing gleam of light would ruin a nitrate bath. We have never experienced any evil result from such a cause. It is as well, however, to keep the bath generally in the dark; any evil which could result would arise from the presence of organic matter in the bath, which light would tend to reduce. 3. It entirely depends upon the mode of intensifying whether it may or may not be done in daylight. With bichloride of mercury, sulphide of potassium, &c., you may work in daylight; with pyro and silver, it is better to work in yellow light, as white light, acting upon the silver, will soon make the pyro and silver turn turbid, and will sometimes cause reduction on the shadows, and fog.

XENOPHON.—The stains on your negatives arise from the use of an energetic developer, which you do not contrive to make cover the plate at once in one even wave. Until you get more skill in covering the plate with the iron solution at one sweep, use it a little weaker, add a little more acetic acid, and also a little more alcohol to prevent the solution running from the edges of the plate in greasy lines. 2. A little more exposure would have improved the negatives; and, with a weaker developer and more acid, you would have less risk of reduction on the shadows. 3. We not know much of the lenses you name, but believe them to be pretty good for low-priced lenses.

SPIRIT PHOTOGRAPHS.

WE feel that some apology is due to our readers for gravely occupying their attention with what we now do not hesitate to style a pitiable delusion originating in shameful fraud or mischievous trickery. Our business is not, however, with the general claims of what is termed "Spiritualism," but with a phase of it in which our own art is prostituted to purposes of imposture, and which we feel called upon to lay fully before our readers, if not to denounce. The chief details have already appeared in our pages, and, as no new facts have transpired, we shall not exhaust the patience of your readers by a repetition of evidences similar to those already published. The faith of photographers in this country has, however, been challenged on new ground. Copies of the photographs containing the alleged spirit-portraits have been announced in our advertising columns for sale in this country, three for three and sixpence, in sealed packets, like some other matters of more than questionable character. In addition to the evidence thus to be derived from sight, the *Spiritual Magazine* claims especial attention and credence for a letter from Dr. H. T. Child, of Philadelphia, who is stated to be well known to "many in this country as a man of science, and a clear philosophical thinker." We demur, however, entirely to his science and philosophy, as developed in the letter in question, for the reasons we shall lay before our readers.

Dr. Child, at the opening of this letter, states that he had been informed that "the learned philosophers who constitute the American Photographic Society had solemnly resolved that the spiritual likenesses are a fraud and gross deception;" he then adds that this led him "rather to infer that these pictures were real because of this decision!" The fact that a body of scientific gentlemen, with no possible object before them but the truth, having examined a subject on which they were pre-eminently well qualified to form an opinion, and pronounced it a fraud, rather inclines this "philosopher" to believe in its truth, and in this spirit he proceeds to investigate the subject. He informs us that he is aware of the modes in which the spirit photographs might be simulated, one of which is to place another negative in contact with the sensitive plate, already containing a latent image of an actual sitter, and allow the light of a lamp to pass through the negative. So far so good. But the doctor then proceeds to illustrate his character as a "man of science," by informing us that he has seen a photograph so produced, and that it was distinguishable from the genuine spirit photograph by having "a very marked yellow tint, the result of the artificial light of the lamp!"

With these two specimens of the doctor's knowledge of facts and mode of reasoning upon them, his "science" and "philosophy," we presume our readers will be content. One word more, however, since it bears on the theory of photography, and introduces ideas doubtless new to our readers. Some of the doctor's spiritual visitants have communicated

to him the theory or *modus operandi* of these spirit portraits. Here it is:—

"There are three forms of matter. First, tangible matter; second, the imponderables, well known to science as heat, light, electricity, magnetism, the Od force and the life principle. These become more refined in the order in which I have named them, and thus approximate toward the third realm of matter, which constitutes spirits, and the home they dwell in, in the spiritual world. Photography, or the art of printing by light, is the most spiritual of all the arts, and by it any substance that is sufficiently dense to set in motion the rays of light, may have its form and character printed on the plate, being received there by the delicate and perceptive chemicals which are used. But spirit forms are so much more refined than light, that they cannot set in motion or reflect its rays. To do this, they require the aid of the life principle—the Od force—magnetism and electricity. These may be obtained from certain mediums, and the atmosphere around them; and when thus obtained and properly placed, either around a spirit form, or combined and formed into such a model as to represent the form itself, either of which will be enabled to set in motion the next form of matter, which is light, and print an image upon the glass. It does not require as much light to print this as it does to make an image on the retina of the human eye, and hence these forms are not visible. This model process is the one which will be first introduced, and hence the forms of spirits and objects will not be very perfect."

One or two words on the "spirit" portraits sent to this country and advertised for sale. When we saw the announcement, we called upon the publisher and asked to be permitted to see the pictures in question. We were informed that strict instructions had been given that no one was to be permitted to see them without purchasing. They were in sealed packets, and could only be seen on disbursing three shillings and sixpence. As these instructions emanated from the proprietors of the *Spiritual Magazine*, who have undertaken the speculation of getting up these pictures for the English market, we were scarcely so much impressed with their desire to promulgate what they believed to be spiritual truth, as with their anxiety to obtain material cash. However, we purchased the packet, and although we were prepared for imposture, we were altogether confounded by the barefaced humbug revealed to us.

The first picture contains a portrait of Mumler, the "medium and photographer," standing with his hand on a chair. In the printed description at the back it is stated "in the chair sits a half-defined female form," and that "this was at once recognized as a deceased relative." The half-defined female form is simply and palpably, to the eye of any experienced photographer, the smudgy trace of a former image on an imperfectly cleaned plate, not sitting on a chair, but near it. She is attired in the ordinary costume of the material world as worn in the nineteenth century, and sitting in the conventional position, with one arm on the table holding a book and the other laid across a lap, as doubtless Mr. Mumler is in the habit of posing young ladies. It is such an image as almost every photographer of any practice has occasionally been troubled with, the persistency

of the image on some samples of glass being very singular. An eminent photographer informed us the other day that he had a plate which every time it was used gave traces of the portrait of the late Prince Consort, which had once been taken on it; and there are various similar cases on record.

The second picture is a portrait of Mr. Alvin Adams, stated to be known as the great express agent of America. By his side and partly mixed up with his figure, is the smudgy and indistinct image of a boy reading, which is stated to be recognised as the portrait of a nephew who has been dead a few years. The same general remarks apply to this as to the preceding picture.

The third is a portrait of Mr. Luther Parks, of Boston. The "spirit" figure here bears the evidence of intentional imposture. The other images are as we have stated evidently the result of ill-cleaned old plates, and may have been produced by accident, and afterwards presented as spirit photographs in joke until, in the eyes of credulous persons, they assumed the aspect of supernatural visitations. The trick "taking" must be repeated and improved upon; and in the picture of Mr. Parks we have an illustration of the attempt. Here a figure is introduced bearing some resemblance to the conventional and time-honoured ghost; it is robed in flowing white drapery, with something like a nimbus, or it may be a fancy night-cap above its head; one arm is extended and holds something like a wreath which is offered to Mr. Parks, who appears quite unconscious of the favour. The general position and aspect of the figure reminds us of allegorical paintings of Victory crowning heroes. This figure, we are informed, is recognized by the family as a "strong" likeness of a deceased nephew. Now, as the face in the picture has not a trace of a feature, but is simply a round white patch, without any indication whatever of the human face divine, rather resembling the white paper dolls cut out occasionally for children in the nursery, we can only come to the conclusion that it was the most extraordinary "nephew" we have ever seen, or that "the family" are considerably more imaginative than the Yankee horse which, having green spectacles put on, fancied he was at grass when he was eating deal shavings.

Seriously speaking, we feel very indignant that our art should be brought into disrepute by being made subservient to such an impudent trick. We are told in the *Spiritual Magazine* that the whole is a matter of evidence, meaning testimony, and not of probability or theory. We reply that there are some things which are not believed on testimony, and that there is some testimony not worthy of credit. We should not believe a man who informed us that the moon was made of green cheese, although he told us that he had been there, and subsisted for a month on its cascos products. These photographs present internal evidence of their mundane source, stronger than all the testimony as to their spiritual origin. And we protest against the blasphemy offered to man's spiritual nature, in attributing these abortions to such a lofty origin.

We are somewhat amused to find at the conclusion of the article in the *Spiritual Magazine* the following remarks: "of course the *Photographic Journal* of London is true to its instincts, and denounces the whole as a shameful imposture," &c. Now, as the *Photographic Journal* did not offer a single comment on the subject, we presume that the *Spiritual Magazine* is confounding us with our esteemed contemporary, and as a challenge follows, we feel bound in fairness to take up the gage. "We invite these gentlemen," says the *Spiritual Magazine*, "to produce likenesses of the deceased relatives of their sitters, whom they have not previously known, and without the collusion of their sitters, in the presence of honest and experienced investigators, who shall not be able to detect the imposture." When the editor of the *Spiritual Magazine* will furnish us with sitters, and investigators who will be willing to accept patches of white paper without a trace of feature, such as the image of Mr. Luther Park's nephew, as "strong likenesses," we shall unhesitatingly produce any quantity of such likenesses.

THE NEW GLOBE LENSES.

We have recently had opportunity for a hasty examination of some of Harrison's new globe lenses, regarding which extraordinary statements have been made as to the amount of angle they included. We knew that some of Harrison's lenses were very good, having used one we purchased in New York for years. But we must confess we were disappointed in these; not so much at any special faults in the lenses as in the discrepancy between their actual qualities and those claimed for them. It was stated that the new lenses would include an angle of 90° on a flat plate; and that they were very rapid. It has been more than once stated, the stereo lens of this form having a focus of two inches and a half, would produce a picture of five inches square. We had no opportunity for any very accurate examination or trial, but we will record the result of a hasty inspection.

The combination consists of two meniscus lenses placed with their convex surfaces outwards, and so arranged as to form segments of a perfect sphere. They naturally present a somewhat unusual appearance, and are mounted in what appeared to us an unnecessarily heavy and clumsy bronzed mount. The stops, five in number, are fixed in the centre, all being in one plate, each one in succession being brought into position by the rotation of the plate.

The stereo-lenses have a back focus of $2\frac{1}{2}$ inches, the equivalent focus being about $3\frac{1}{2}$ inches. The circle of light produced is about five inches in diameter, but it is very unequal in intensity, being bright in the centre, and falling off considerably towards the edges. The extent of good definition, however, even with a small stop does not exceed the size of a stereoscopic plate, or about $3\frac{1}{4}$ inches square. The first fact which struck us was, when using the largest stop, the want of a crisp, fine definition, or precise focus anywhere, arising from the existence of a considerable amount of spherical aberration. To secure good definition a very small stop was necessary; and as with the largest stop the amount of illumination was very small, the use of the lens is necessarily limited to subjects permitting long exposure.

For the purpose of obtaining a comparative view we mounted one of the globe lenses and one of Dallmeyer's new stereo lenses on the same camera, so arranging them that the image of both, when in focus, fell on the same plane. With the globe lens we used the largest stop, which is about a quarter of an inch in diameter; with the Dallmeyer a stop of about three-eighths of an inch. With these stops the amount of illumination was nearly equal, but a little in favour of the English lens. The definition in the globe lens was very much inferior everywhere. It was a dull, foggy day, requiring a wet collodion plate requiring an exposure of about a minute and a half. The image given by the Dallmeyer lens was sharp and crisp and well made out, that by the globe lens was altogether fuzzy. In the latter there was, however, the considerable depth of definition which arises from spherical aberration. The margin of the plate also showed considerable astigmatism.

We also made a hasty examination of one of the larger lenses, the back focus being 8 or $8\frac{1}{2}$ inches. We did not try this lens, but examining its image on the ground-glass we observed the same want of crisp definition as in the smaller lenses. The equivalent focus was about 11 inches; the circle of light included about 15 inches, or a little under. A Dallmeyer's No. 1 triple, with equivalent focus of a fraction under 8 inches, gives a circle of light of 12 inches, showing the extent of angle included decidedly in its favour.

For instantaneous, or even ordinary rapid work, these lenses appear to be altogether unsuited; and for ordinary stereoscopic work they have the defect, incident upon a very short focus, of giving a very violent perspective, or rapid convergence of the lines. But as they give perfectly straight lines, they will be occasionally useful for archite-

tural work in confined positions where a very short focus becomes valuable. Thus for interiors they may occasionally be useful, their depth of definition becoming a valuable quality, especially if the amount of illumination will permit the use of a small stop, and thus secure sharpness. For general use, however, they are decidedly not equal to some of the recently invented lenses made by English opticians.

ENLARGED NEGATIVES.

THE prints from enlarged negatives exhibited by Mr. Alfred Harman, have excited much interest amongst photographers as being much finer than it was believed possible to obtain by such a method. The principle and the method of working have been often described in our pages; nevertheless, a few words from Mr. Harman will, doubtless, interest many, and we have asked him for details of his manipulation. Here they are:—

"Dear Sir,—In compliance with your request, I send you a few particulars of the method used by me to enlarge negatives.

"The negatives most suitable for enlarging are those which have received a very full exposure, but have not been sufficiently intensified for ordinary printing purposes. But by judicious management it is possible to get very fine results from negatives which have been taken expressly for printing from. The enlargements exhibited in Suffolk Street by me were enlarged for negatives which had been used for printing a large number of copies. I mention this to show what can be done by this method.

"I will now proceed to describe the apparatus I employ; but to save any description, I have only to refer your readers to some numbers of the PHOTOGRAPHIC NEWS, which appeared a month or two back, where Mr. Samuel Fry described a method of enlargement he introduced for his own practice. My apparatus is identical in principle with his, and I here take the opportunity of thanking Mr. Fry for his very ingenious contrivance, and the liberal courtesy with which he has made it known.

"Now for a few words upon the process. I need not mention that the small negative must be *perfectly sharp*, if not, the loss of sharpness apparent in the enlarged negative will be very great.

"The transparency must be of the same photographic value as the small negative; that is, there must not be any very great contrasts, or the large negative will differ.

"I generally take the transparency a trifle larger than the small negative, but that is a matter of not much importance.

"It is better not to varnish either the original or the transparency, as there is very often a quantity of minute particles in the varnish which do not show in the small negative; but, when enlarged, the effect is, of course, the same as putting them under a microscope. I do not mean to say a good enlargement cannot be made from a negative that has been varnished, but it is better when they are taken with the view of having them enlarged, not to varnish them.

"For large plates, it is necessary to have a support in the centre, while the collodion is being poured. I have a ball and socket arrangement, which I find answers extremely well; the same stand can also be used for developing.

"The bath I employ for large plates is a large deep tray, with about four inches at one end covered, so that when tilted to that end, the well formed will hold the solution. Four pegs stand out from the bottom to support the plate, and prevent its touching the solution, until the bath is lowered to the vertical position, when the solution flows evenly over the glass.

"The development, fixing, &c., are the same as used for ordinary wet collodion.

"In conclusion, I must remark, that it is *positively* necessary to have a room fitted expressly for the purpose, and used for that purpose alone.—Yours very truly, ALFRED HARMAN."

PRINTING DIFFICULTIES.

BY A PHOTOGRAPHER'S ASSISTANT.

WHEN the system of alkaline toning was first introduced, it was generally considered that excessive alkalinity was essential to secure satisfactory results, and quantities of soda, varying from 5 to 10 grains to the grain of gold, was recom-

mended, without one thought being directed to the diversified character of various samples of the tetrachloride of that metal prepared by different makers. The existence of this salt as a tetrachloride was perfectly understood, but the ever-changing quantities that may be traced even in samples prepared by the same maker was considered a matter of too little importance for investigation, and here lay the root of the many failures that characterised toning operations at the period before alluded to. Happily, patient, untiring observation and research have been, and still are, directed to this subject, and we now understand the necessity of avoiding excessive alkalinity in our toning solutions; for under such conditions toning operations may be pronounced a tediously uncertain process. It should therefore be remembered that what I have termed a decidedly alkaline bath must not be taken in its chemical meaning, but rather that condition when the free acid, introduced with the gold, is neutralised by the soda leaving a trace of the liberated carbonic acid, whose presence can only be detected when the litmus paper is in a perfect condition as a testing medium, and I once more emphatically repeat where heat is employed in the manner I have recommended, except a trace of free acid be present, toning action will prove too slow for commercial purposes. There would appear at first sight a striking analogy between the toning and linen bleaching operations, more especially when chloride of lime is employed in the latter process, the operation of each being hastened by the presence of a free acid; the lime in this case liberates chlorine in favour of the acid, but this explanation would not hold good in toning operations, for the fact of gold remaining in solution in the presence of large quantities of free acid, through whose agency it resists decomposition, proves that the acid can exercise no influence in promoting or producing decomposition. But from the facts we have enumerated it is obvious that it has a strong tendency to increase the bleaching powers of the chlorine by directing its action to the surface of the paper and preventing its combination with the soda, as it is wont to do when this substance last named is added in quantity sufficient to overcome the influence of the acid. It is a judicious observance of this bleaching process that enables the printer to secure satisfactory results, as its duty is to prepare the way for the gold. The operation of toning action may, in some respects, be compared to the electro-gilding process, but moved by a power entirely different in its composition, whose nature in the present state of chemical science is but imperfectly understood. For convenience sake we call it affinity; at all events, it is not electricity, for it is a well proved fact that a current of the electric fluid passed through or brought into contact with water containing chlorine, will, by its decomposing action on the water, produce hydrochloric acid, the chlorine uniting with the liberated hydrogen, thus forming the acid named; so that a bath would become more and more acid as toning proceeded. That such is not the case may be easily proved by any person who may feel an interest in the subject.

In the absence of a diagram, we may endeavour to explain our modified views of toning action as follows:—Chlorine entertains a great affection for soda, and would willingly fly to its embrace, but ere she can approach near enough to do so, acid steps between, and combining their forces together, they attack the surface of the paper, thus preparing it for the reception of the gold, and atom after atom is attracted and deposit themselves on the spots thus prepared. If the surface of the paper is not perfectly free from the unreduced, or, at all events, unstable nitrate, it assumes a false colour that dissolves out in the hypo bath; and the same results follow when chlorine is liberated in large quantities, a false colour is produced without a proportionate deposit of gold. We have, therefore, two extremes to avoid, an excessive alkaline, or acid conditions. As a rule, the larger the amount of chlorine the greater the quantity of soda required, and the greater the amount of chlorine liberated by heat, the stronger the necessity for free acid, the quantity being

regulated by the amount of reduction required. Having now said as much as is necessary on the treatment of highly albumenized papers, I shall proceed to treat on the lighter samples, which, with a few words on the numerous failures produced by the agency of water, I shall bring this paper to a conclusion.

(To be continued.)

ON THE PRODUCTION OF INSTANTANEOUS PHOTOGRAPHS ON LARGE PLATES.

BY LIEUT. COL. STUART WORTLEY.*

I SHALL begin by mentioning that, in the short paper I am about to read to you, I shall avoid as much as possible entering into details of manipulation, &c., all practical men having their own way of working.

I may, however, start by impressing upon every one the absolute necessity of clean plates, both for the sake of avoiding marks in the original negative and to guard as much as possible against loosening of the film during the intensification. The collodion I have been in the habit of using is very alcoholic, the following being the proportions:—

Ether	1 oz.
Alcohol, 802	2½ oz.
Iodide of lithium	15 grs.
Bromide of lithium	6½ grs.

or rather more than double alcohol to ether, between 4 and 5 grs. of iodide and 2 grs. bromide to the ounce of collodion. The pyroxyline is first steeped in the iodo-bromized alcohol, and the ether then added. The quantity of collodion varies very much in different samples. I thus obtain a very fluid collodion, which I find a great advantage in coating large plates where a very even film is required, and in all instantaneous pictures where there is much sky.

The utmost precautions must be used to avoid streaks, spots, or stains of any kind. This is one of the great difficulties of working out of doors. I have lost many good negatives by accidental spots from dust, and such unavoidable causes.

The silver bath is made from Hopkins and Williams's pure recrystallized nitrate of silver, 35 gr. to the ounce. I iodize by leaving a couple of coated plates in the bath for several hours.

I then find it necessary to add from 2 to 3 drops of pure nitric acid to the ounce of bath. The more bromide in the collodion, the more nitric acid, I find, is required in the bath. I leave the plate rather longer in the bath than I should were I using simply iodized collodion, as I find the maximum of sensitiveness takes longer to produce with a collodion containing much bromide than with a simply iodized or lightly bromized collodion.

I drain very carefully, and place blotting paper all along the bottom of the plate when in the slide.

My pictures in the Exhibition are taken with Dallmeyer's triplet lenses, and usually with full aperture,—necessarily so when facing the sun, as any diaphragm in the lens produces rings on the plate, when the sun shines into the lens.

My developer I make as follows:—

Sulphate of iron	20 ounces
Distilled water	120 „
			Dissolve.	
Acetate of lead	0½ ounce
Water	5 ounces
			Dissolve.	

Mix the above solutions, and when the precipitate has all settled, decant off very carefully. Add—

Formic acid	5 ounces
Acetic ether	1½ „
Nitric ether	1½ „

* Read at the London Photographic Society, Feb. 3rd.

This I keep as a stock solution, and filter off as much as I require for use at a time, adding acetic acid in proportion, according to the temperature of the weather and the class of picture required. The developer should move freely over the plate, and should remain on the plate some seconds before any sign of the picture appears. As the acid loses its restraining power, the iron acts, and the result is a simultaneous action over the whole plate, and the picture flashes out all at once. You will have noted that the developer is a very powerful one, and I use a very liberal amount of acetic acid as a restraint to the energetic action of the iron and formic acid.

I keep the developer on the film till I have obtained the necessary detail, and then, washing the plate very thoroughly, bring it home in a grooved box, to be fixed in the evening with a weak solution of cyanide of potassium. (Many of my negatives were taken in Italy, and brought home, after fixing, for the intensification to be done in England.) The edges of the plate must be carefully varnished, and the film moistened with distilled water. A saturated solution of bichloride of mercury is then poured on, and poured off as soon as the film has taken the proper colour, on which, after a good washing, a five grain solution of iodide of ammonium in water is poured on and off till the desired depth is attained. I then use two solutions composed as follows:—

1. Pyrogallie acid	12 grs.
Water	1 oz.
2. Citric acid	50 grs.
Nitrate of silver	10 grs.
Water	1 oz.

Pour a few drops of No. 2 into No. 1, and pour on and off. The negative can now be made to assume any depth you may require.

If you have a negative from which you desire to print vignettes, keep the negative tolerably transparent. If you intend to print your negative to the edges, see that it has force conjoined with softness. Many a negative, which is too transparent to give an effective print if printed to the edges, will give a beautiful vignette.

Every one should print from their own negatives. Taste and knowledge are shown as much in the printing as in the production of the negative. Many amateurs who produce moderate negatives send them to professional photographers to print, and thus obtain the taste and talent of another man in the production of the pictures, which they then speak of as their own. This is not, in my opinion, at all right, as the printer certainly deserves to share the credit of the finished picture.

I use, for printing, a silver bath of 100 grains to the ounce of water, acidified with citric acid; and use as toning-bath a solution of chloride of gold and phosphate of soda, of which I keep a large quantity in stock, and prefer to use some weeks old. I fix in fresh hyposulphite of soda, and mount the finished picture with fresh starch.

ON THE MANIPULATION, DEVELOPING, AND INTENSIFYING OF NEGATIVES.

BY JAMES EWING.*

In looking over the papers read before the members of the late and present societies, it is a strange fact that we have never discussed the above important divisions of our chemically pictorial vocation, although, in point of routine, they should have had precedence of our papers on printing, toning, &c. But should the disquisition on the heads proposed for your consideration prove as successful in eliminating general good to the profession as discussions on some of the papers previously read, we shall not be sorry in passing the evening conversing together.

The enthusiasm arising from the beauty, and wonder excited in the versatile French mind, and, indeed, that of the world, by the introduction of the Daguerreotype to the Academy of

* Read before the Glasgow Photographic Association, Feb. 5th, 1863.

Sciences, in Paris, by M. Arago, had not yet reached its acme before the celebrated Mr. Fox Talbot had forwarded for the inspection of the members of that august assembly his sun-made Calotypes: dingy they might be when compared with the brilliant Daguerrotypes, but rich in that promise which M. Bist almost prophetically conjectured, that from those murky shades, with certain modifications, should yet spring the beautiful pictures of to-day.

Whilst admitting the beauty of the Daguerrotypes, its salient points could not be hid: these were principally the danger attendant on the accumulation of plates, &c., used in the mounting of the pictures, the inconvenience of binding them into suitable forms for publication, or other art purposes, as also the objectionable reversion of the image. The Calotype, then, first presented to the photographer a medium by which he could produce, in a kind of way, copies from his first impression; but whilst it pointed to the possibility of overcoming the difficulty, it did not entirely succeed; and, until the introduction of albumen and collodion on glass, nothing of a presentable photograph on paper could be obtained. On the adaptation of Mr. Talbot, however, depended our after success in the production of the negative, his task being to impregnate paper with the salts of the elementary substances used by Daguerre in the production of his image, viz., iodine and silver. The formation of a negative on such paper is the high honour due to Mr. Talbot, but not for the discovery of the latent image, or the agent for development thereof: to give that gentleman such honours would be gratuitously bestowing on him that esteem which legitimately belongs to others, though to Mr. Talbot we are really indebted for our first approach to the negative. But it is still a nice question, which must be decided sooner or later, whether Niepce or Daguerre first produced by a lengthened exposure an apparent image on a sensitive surface, which, by a shorter exposure, was capable of holding the image invisible till developed by some other agent, or, in other words, how was the latent image discovered. After the introduction of glass and collodion, it must be remembered the many difficulties that had to be encountered, producing the negative, the great feat being how to intensify the positive. In a paper read by Mr. Brown to the old society, and one by myself on the positive process, we glanced at the obstacles the amateur and professional had to contend with in their pursuit of the art, as also the introduction of the different formulas, by which we arrived at the production of good pictures on glass; but whilst we were practising successfully and openly the glass process, we were at the same time quietly studying how to intensify. I remember our old daguerrotypes mercury boxes being converted into pans, for the fuming of the positive with sulphur, just as the milliner's girl introduces her idol straw bonnet to be whitened, only ours was the reverse process, it was with the intent to blacken our idol. Having glanced at the discovery and discoverer of the negative and positive from the negative on paper, I take this opportunity to remark, that in an art like ours, where so many differing points are, as it were, brought to a focus, individual effort, such as it may overcome, is brought to a stand-still, and he who would prove a practical and successful photographer, must not work alone, but by a methodical arrangement, to harmonise all these points involved in the art, that step by step each particular part of the process shall be executed with that precision and care which photography demands, the neglect of which in the slightest instance casts a shade over the fair face of the delicate creations. When we consider the multiplicity of operations through which a photograph passes in these days, and the nicety and delicacy with which those operations must be performed, can we wonder that individual effort, however energetic, could successfully compete with an institution regulated by a comprehensive division of labour, where every hand skilled in its own set part executes faithfully the task allotted it without constraining or forcing? Certainly not; and hence, those establishments where this particular is most stringently observed, in America, France, or Britain, have been the most successful, both as regards beauty of result and honourable remuneration. It is important, then, with an eye to the perfection of result, that the manipulation of the negative shall be conducted in as careful and deliberate a manner as possible. This general head involves a great many nice points, more than any casual observer would suppose: the kind of glass best suited for the basis of the negative; the temperature (an important feature); at which the suite of photographic rooms should be kept; the light in the glass-house, and more particularly the colour and quantity of light admitted into the sensitizing

room; the quantity of the silver bath; the strength of the same; whether the pure nitrate in solution or saturated with bromide or iodide; whether alkaline, acid, or neutral; how to strengthen when weakened; method of pouring on the collodion, setting, placing in the silver bath, time of immersion of in the same; draining, placing in the dark slide, and time of exposure.

The kind of glass to be used; on this head a variety of experiments exist, as to whether colourless plate, patent plate, flatted crown, or common glass, is best suited for the purpose. The weight of opinion in the matter preponderating in favour of the patent plate, the colourless glass being objected to on account of its softness, difficulty of getting its free from scratch, and its tendency to absorb damp under the varnished film, producing cracking in the negative. Flatted crown is often used as successfully as plate, but is more subject to break, on account of its thinness, and more difficult to clean; all the objections to the other qualities are labelled against common sheet, and yet I must say I have seen good negatives taken on all these kinds of glass; but there is no doubt to be entertained against the fact of plate glass being the glass for negative purposes. In cleaning the plate the old and unsurpassed system of steeping it in a dilute solution of nitric acid and water, still holds good, rinsed well in pure water, and stood up to drain, dried with cloth No. 1. After which apply the iodine pad, moist with iodide solution, composed of metallic iodine dissolved in a solution of iodide of potassium and water, but add no muriatic acid, as the slightest trace left will generate acid, and form an appreciably small quantity of chloride in the sensitizing bath, which often becomes a source of great annoyance, destroying the extreme sensitiveness of the bath, and causing minute holes in the collodion film. After having obtained a flat polish with the other cloths, pour on the collodion. Operators of standing differ on the best method of doing this, some pouring the collodion on from the right edge corner of the plate, others from the left, whilst others are of the notion that pouring on the centre, especially in large plates, gives a more equable coating, which ever way is best, the end in view obtained is all that need be cared for, viz.:—A flat even coated surface of collodion. After slightly setting, according to the nature of the material used, whether alcoholic or ethereal, place the plate on the dipper, to this all agree, although some discussion ensues as to the proper mode of placing the plate in the bath, some supposing that the plate, if longer than broad, should be immersed long ways; the why being answered, as the collodion is poured, so should the plate be inserted in the bath. Now, I think, theoretically and practically, this mode is incorrect, as by immersing the plate broadways, that is, when using a vertical bath, it has all the better chance of being covered with the nitrate solution, as it is the nature of ether and alcohol (being of less specific gravity than water) to rise to the top of the bath, thinning the solution, and giving an uneven coating of iodide of silver. But to those whose baths will not permit of their being inserted broadways, it may be observed, that, as generally in pouring on the collodion, one side of the film is a little thicker than the other, it will be best to insert the thinly-coated portion downwards, so that the upper portion being possessed of more iodide and consequently more absorbent of the silver, shall get but its due proportion. We are not of opinion of M. D. Van Monckhoven, in a recent paper translated into the *British Journal of Photography*, that after a little practice, the operator will be enabled to work in absolute darkness; although we believe in a very subdued yellow light being used in the sensitizing-room, and all care taken that no dust be raised during any of the operations therein; and whilst we insist on care and attention to every little point in the manipulation of the plates, we would not have you believe that "every operation in the collodion process should be performed as if you were working in the den of a sleeping tiger," as insisted on by the author of an article on photography in *Orr's Circle of the Sciences*. The time of immersing the plate in the bath is another question involving some controversy, the general method practised, and as given in photographic manuals, being till all the greasiness has disappeared. Now, Mr. Brown, in his paper on the Positive Process, touched on this head about two years ago, and showed that different results were obtainable by leaving the plate for a shorter or longer period in the bath; and not long ago Mr. Macnab adverted to the same subject with regard to negatives, and I think there is no doubt in the matter, as it is quite obvious that a collodion containing iodide alone will take less time to excite than a bromo-iodized plate, whilst either may

be influenced by a longer or shorter period in the bath. Then the point is to secure the plate at that moment when it is in the most sensitive condition, a matter requiring patient watchfulness in practice, but having obtained that important point with an unvarying temperature and light, negatives of nearly the same quality and density may be obtained for days together. Some assert that the plate should lie in the bath undisturbed for about one minute, then slightly moved about and again allowed to rest, till all the alcoholic streaks have disappeared. Now, I think and believe, if the plate could be kept moving in the solution all the time the sensitizing is going on, that a more equal surface would be the result, as it appears to me that when a plate is inserted in the bath the tendency of the alcohol and ether is to rise in streaks over the film, whereas, by moving it, say, with a circular motion, the evaporation is dispersed in the solution with less hurt to the plate. You will observe streaking more particularly as the bath weakens and becomes more saturated with alcohol and ether. Some use their baths in the old proportion of 30 grains to the ounce of water, without the addition of any iodide or bromide; others from 36 to 40 grains with such addition; but I must say I have seen as pretty negatives produced with a 30-grain bath as with either of the former; but the strong baths have this recommendation in their favour, they last longer. Some are of opinion that a neutral bath works best, with some collodions this cannot be doubted, but it has always a tendency to fog. Some prefer an alkaline bath, supposing that thereby they secure a film peculiarly sensitive to light; and, if we can place any faith in those instantaneous workers in the sun, and we have little reason to doubt them, it must be allowed they have all a leaning to the alkaline side of the question; but, for good, clean working, with an average exposure, that can be counted by oneself without annoying the subject, give me a slightly acid bath, as it has less tendency to fog than those previously mentioned. The time of exposure depends on the kind of negative required. I do not think that a large picture requires such a long exposure as a small one; but to get out detail and shadow, and to avoid those shocking contrasts of coal and chalk it is necessary to over-expose considerably; by doing so the high lights mellow into the secondary tints, whilst it imparts to the resulting picture soft lights in shadow. I think a slight over-exposure in the case of negatives for *cartes de visite* is a fault less heinous than under-exposure, or sometimes with a little management, in after intensifying, the "all overcrishness," so to speak, can be remedied.

Now there are a variety of developers, those principally in use are pyrogallic acid, gallic acid, and iron, into which the acetates and nitrates of other salts are introduced as accelerators or retarders. The gallic and pyrogallic acids, although yielding good negatives, being very slow of action, do not on this account receive the same favour in the eye of the professional photographer, as the plates manipulated with those acids require much longer exposure, and a greater amount of care and time in their development. The iron, being the most rapid developer, is the favourite, and the different formulæ for making up the various baths from this salt would occupy too much time in the rehearsal; suffice it to say, that the usual bath of protosulphate of iron solution, from twelve to fifteen grains to the ounce of water, with the usual amount of acetic acid and alcohol, is capable, when you have a good light, of producing negatives from the camera, without further intensifying. Now, the manner of pouring on the developer becomes a matter of argument also, some contending that it should be poured on as the collodion is poured; as the plate is immersed in the bath and lifted from the slide, I pour on the developer as I pour on the collodion, but not as the plate is inserted in the bath. In flowing the iron solution over the plate, it should be done as rapidly and evenly as possible, else streaks and stains will result; keep the solution moving on the plate, say, with a circular motion, till the detail is just out, and all the greasiness has disappeared; it should then be washed well under the water tap, care being taken that the strength of the water is not too great, as it is apt to exfoliate the film, which may yet be required to pass through an intensifying process, and as such, is likely to lift the collodion off the plate. The less the film is loosened, the better.

In the matter of fixing, there is also discussion involved, and the great question in this case is, which of the two substances, hyposulphite of soda, or cyanide of potassium, is the best and most expeditious agent in the removal of the unreduced iodide

of silver, the argument in favour of hypo being that it costs less, and is less deleterious to health; but I think (even admitting such to be correct) that cyanide is the best and cleanest fixer, clearing away all the organic matter that only serves to clog the pure image, allowing an intensifier to mingle at once with the metallic body, and clearing the blacks better than the hypo. From experience, I know that if you intensify after the plate has been fixed and dried, using iodine as a medium, you will find it much harder to get the pyrogallic solution to mingle with the silver, and further, after washing well (and it requires an immense washing to clear the film of the hypo), it is subject to crystallize under the varnish; and again, when your fingers are in the slightest way touched with hypo, dare you work near the silver bath, or touch prints on paper without leaving a trace of your whereabouts?

I look upon hypo-sulphite of soda as a very dangerous compound in the operating room. You can readily wash cyanide from your hands, as it has an affinity for moisture, but you will have some difficulty in removing the last trace of the hypo bath; more especially if any oxide stains are on your fingers. I am, therefore, of opinion, that friend Cyanide, though a dangerous fellow to drink, is the sharpest fixer, and those who would work expeditiously, for "time is money," should hold on by Cyanide.

If it were possible, always to develop the negative at once with iron, I think we would have the perfection of results, as those pictures which are done in the field, right from the camera, are indeed the most beautiful. In them "Ilka blade o' grass" has its *due* share of intensifying from the moment that the photographic sunbeam darts from its tender stem. I would avoid all after intensifiers, as they have a tendency to attack the finer gradations of shade, eating up those tiny tints which make the nature picture most valuable, intensifying those bolder lights that can resist their action, and, on the whole, swelling disproportionately the finer lines of the picture, I have no doubt but that yet we shall be enabled to do so, and then we shall bid farewell to those old intensifiers, to which we have been indebted in the past, and are still indebted, in a fix, to give our fair subjects the Ethiopian wash. The oldest intensifier with which I worked was the fumes of sulphur; then was introduced bi-chloride of mercury in conjunction with iodide of potassium, pyrogallic acid, gold, hydrosulphate of ammonia, ammonia. I show from the negative debris of the past specimens of the different intensifiers, but how simplified became the process of intensifying when it was made known that pyrogallic acid, with a slight proportion of silver solution, could still be precipitated in fine division, even after fixure. It gave photography on paper an impetus that no other intensifier had done previously, and until, as I said before, we can develop an image direct from the camera with iron, it must continue to hold supremacy over all other intensifiers with which we are yet acquainted. But even here we have a moot point for controversy amongst our ablest photographers; some contending that it is better to intensify the image before fixing, as if there is any detail not brought out by the iron, it is sure to come out with the pyrogallic acid, I have tried this method over and over again, and although occasionally successful, still I was never sure when I had arrived at the proper pitch of intensity, owing to the manipulation being done under cover of the yellow light, as the yellow film of iodide caused it to look denser than it really was, and often when the picture was fixed, it was only to find it coated with a precipitate of silver, either above or below the film; now it is a waste of time to intensify a picture that you do not know is worth intensifying or no, those are my objections to that mode, although I know many gentlemen who work it successfully. Others are of opinion that the pyrogallic solution should be added when the picture is just fixed; a very good mode; and I think, with all due deference to those who think otherwise, it is preferable to allowing the picture to dry before intensifying, because if the collodion shrinks in drying, as undoubtedly it does, it gives a sharpness to the detail, that can never be possessed by a picture that has been intensified after drying. Those who intensify their negatives after drying, are of opinion that they have a sharper or harder image to work upon; and there is no doubt they have, as the pictures have not been intensified previously; but when you coat a beautifully sharp piece of chased or carved work with paint, you take away materially from the sharpness thereof. It is covering the sword with scabbard; whereas if the pyro and silver had been added when the collodion and silver were in a porous condition, the effect of the intensifier

would be to surround the molecules of silver more completely, and fill up the interstices between them, thus binding the image more closely together, which, on drying, shrinks with the film, making a more compact picture. However, it has this drawback, if the collodion has any chance of being crapy it shows it more so than in the other case. In reference to drying pictures, I think it proper to observe that as the heat exercises a double effect on the negative at this stage it should be carefully dried; we know that the film shrinks with the drying heat as also that the glass expands. Now if the collodion be very contractile, the expansion of the glass acts as the great producer of what is called crapy negatives, for I have seen such crapiness displayed by collodions, in which I knew there was the purest material. But could we possibly reduce the image to the negative condition at once, I think the permanence of the negative would be enhanced, the beauty of detail in the softly and gradually blending lights and shadows would be more truthfully given than by our present intensifying processes, as, however small the distortion, it is still a distortion, for we clothe a beautiful subject in a drapery it was never intended to wear.

THEORY OF THE PHOTOGRAPHIC PROCESSES.

BY DR. D. VAN MONCKHOVEN.*

THE photographic processes may be divided into two distinct classes—first, the processes in which silver compounds are used; second, those in which silver compounds are not used. The first deserve principally our attention, because they are used almost exclusively, and because of the numerous investigations of which they have been the object.

1. *The Silver-Salt Processes.*—These can be divided into two categories. The first, including those in which the sensitive surface is exposed to the action of the light for a very short time, and the *latent* image is developed by gallic acid or any other reducing agent. The second, in which the sensitive surface is exposed to the light long enough to produce an intense blackening. In both cases the light acts in the ratio of its intensity, and produces *inverse* images, in which the light parts are reproduced in black, and *vice versa*; but, as in the first category of processes, the time of exposure to the light necessary to produce an image is *very short*, they are used directly in the camera, and in this way a *negative* is obtained. The processes of the second category, on the contrary, requiring a long exposure to light, the sensitive surface is placed in contact with a *negative*, through which the light reaches it, and forms a *positive* or image in which the whites correspond to the whites or lights of the object primitively reproduced. The processes in the two categories are thus very distinct in their uses. We will distinguish them in calling the former *negative processes* and the latter *positive processes*.

NEGATIVE PROCESSES, IN WHICH SILVER COMPOUNDS ARE USED.

Section 1.—Formation of the Image in the Camera.—Although most of the silver compounds blacken when exposed to the light, there are but few amongst them which yield an image by a short exposure, followed by the action of gallic acid or other developing agent. The compounds which possess this property in a remarkable degree are, in the order of their sensitiveness, the *iodide, bromide, and chloride of silver*.

The iodide of silver, being the most sensitive of the three, is used as the basis in the negative processes. It is produced by the action of the vapour of iodine on a surface of polished silver (*daguerriotype*), or by double decomposition in the texture of paper (*albotype*), of a layer of albumen (*albumen process*), of pyroxyline (*collodion process*), of gelatine, &c.

But here we meet with a question on which we have to insist. To form iodide of silver a soluble iodide is introduced in a porous surface, which is then immersed in a solution of nitrate of silver. Now it is possible that the substance which constitutes the porous surface has a chemical action on nitrate of silver, and then we have two silver compounds in contact, and even three, if we count the excess of nitrate of silver which remains on the surface. This is just the case in the albumen and gelatine processes, but not in the collodion process and in the process on unsized paper.

We also remark here a curious fact, and that is that the organic silver compounds in the albumen and gelatine processes are able to yield an image by a subsequent development, when no iodide of silver is present, provided a sufficiently long exposure to light be given. It is also remarked that in these

processes the addition of iodide of silver exercises but little effect, that the time of exposure is always very long, and that the image is visible before the development with gallic acid. The same thing takes place when the pyroxyline or the cellulose (paper) contains organic substances capable of combining with nitrate of silver, and this principally when the substances are albumen (Taupenôt's process) or gelatine (sized paper processes).

To examine how light acts in the negative processes, we will only consider perfectly pure iodide of silver (*daguerriotype*) or iodide of silver in presence of an excess of nitrate of silver (unsized paper)—(collodion).

Two theories are proposed to explain how iodide of silver, exposed during a very short time to light, possesses the property of condensing the vapours of mercury, or of attracting the particles of silver reduced by the action of gallic acid on the excess of nitrate of silver.

1. It is said to be a chemical action.
2. It is regarded as a physical action.

The first theory, which has been presented very clearly by M. Davanne, is almost exclusively adopted on the Continent. The second is due to Möser, and adopted by Mr. Hardwich and ourselves.

Let us analyse M. Davanne's theory. The principal arguments on which he finds it are the following:—

1. The salts of silver in general, the iodide of silver in particular, darkening by a sufficient exposure to light, should, by a very short exposure, darken also, but in an imperceptible way. However, the very small quantity of reduced silver acts as an attractive nucleus on the particles of silver set free by the gallic acid (and probably, also, in the opinion of this author, on the vapours of mercury).

2. If this theory be true, in certain processes in which the exposure is very long, the image will be visible. Experience proves that this happens in the albumen, gelatinized-paper, and waxed-paper processes.

3. Their principal argument consists in the celebrated experiment of Mr. Young, who had exposed an albumenized glass in the camera, and dissolved out the iodide of silver by hyposulphite of soda before developing, and had, notwithstanding that, obtained an image. Thus, says M. Davanne, the light has decomposed a small fraction of iodide of silver into iodine and silver; and the hyposulphite has not dissolved the silver, which, in the development, becomes then the attractive point for the particles of the same metal set free by gallic acid.

Let us examine the value of these three arguments.

1. A film of collodio-iodide of silver exposed to sunlight for $\frac{1}{100}$ th of a second, blackens under the influence of gallic acid, while it does not change visibly in five minutes' direct exposure (that is, if no bromide of silver or no other organic matter than the pyroxyline be present). Thus, let us repeat it, no appreciable change takes place in 32,400 times longer than the time necessary to produce an image by a developer, and notwithstanding that M. Davanne pretends that silver exists there, which is the cause of the subsequent reduction (*vide* our article in *The British Journal of Photography*, 1862, page 340.)

2. Yet in certain processes the image is visible before development. But let us well remark it here, it is precisely in these processes to which we have called attention; because, besides the iodide of silver, there also exists in the film an organic compound capable of combining with nitrate of silver. This is so true that a simple comparison will be sufficient to prove this fact beyond doubt. The collodion process is a hundred times more rapid than the albumen or waxed-paper process; and notwithstanding if an excited collodion plate and a waxed-paper (both with a base of iodide of silver) be exposed in the same camera, and for the same length of time, the collodion plate will show no image when the exposure has been long enough to show one on waxed-paper. But, as the reader will well understand, this image is not produced by the iodide of silver, but by the organic silver compound in the waxed-paper.

3. The third argument, the strongest one of the French theory, does not seem to us more convincing than the others.

In fact, how is it that the collodion plate, which is much more sensitive than an albumenized plate, does not give a trace of an image if fixed before developing, although it has been exposed in the camera for the same length of time?

This is very easy to explain. M. Davanne attributes the formation of the image in the experiment of Mr. Young to the decomposition of the iodide of silver. But that which proves it is not so, is, that an albumen plate without iodide of

* Read at a meeting of the London Photographic Society, Feb. 3, 1863.

silver gives a very vigorous image; and so it is in all photographic processes where an image is visible on removal from the camera.

Let us explain what takes place. In Mr. Young's experiment the film contains *iodide* and *albuminate of silver*. The first is not blackened by the light; the second, on the contrary, decomposes into a brown subsalt, which is soluble in nitric acid and caustic potash. The hyposulphite dissolves the iodide of silver, and leaves, not metallic silver, but blackened albuminate, which causes the development. We were the first to explain this phenomena in *The British Journal of Photography*, 1862, page 340.

According to us, then, no metallic silver is reduced by the action of light on iodide of silver, and no *chemical action* takes place, provided the iodide of silver be not mixed with an organic silver compound. If the least doubt remained in the mind in regard to the fallacy of M. Davanne's theory, the following facts would completely solve it:—

1. If light acts chemically on the iodide of silver in the collodion film, and metallic or suboxide of silver result, an application of diluted nitric acid must dissolve the silver or the suboxide. Now, a plate treated in this way, washed to take away the excess of nitric acid, and covered with a mixture of pyrogallic acid and nitrate of silver, yields an image which, although feeble, is still very visible.

2. Bromide darkens easily when exposed to light; and, notwithstanding that, it is less sensitive than iodide when a developer is used.

3. If the action of light on iodide of silver be a chemical one, it must be in proportion to its duration. Or, to state the matter in a more simple way, if in one second a vigorous image is formed, in two and three seconds it will be twice and three times as vigorous.

Now, in virtue of a singular property of the iodide of silver, it is not so. Light, to produce a maximum of effect, requires a certain time. If this time be overreached, the effect decreases and the image loses in intensity (Möser). This effect has been called *solarization*. This argument seems to us to be decisive.

Let us state here some curious facts discovered by Möser, and which we have had occasion to observe also.

A. A sheet of glass is exposed, behind a piece of paper in which some figure has been cut, to the light of the sun; the breath condensed on the glass will make the action visible.

B. A piece of silver plate gives the same result; but, if for the moisture of the breath we substitute the vapour of mercury, the image can be made visible by a much shorter exposure to light.

C. A copper medal, slightly warmed, is put on a polished plate of silver. The breath of the vapour of mercury will make the image visible, even if the experiment be made in the dark.

D. If the medal be left very long on the plate of silver, or even for a short time under certain circumstances which Möser has not been able to determine exactly (he only stated the fact), the image formed by the breath or mercury will be solarized, and can even be the reverse of the one of experiment C.

This fact presents a striking analogy with the action of light on iodide of silver—action which tends to reverse itself if the action be pushed sufficiently far, and which is indeed reversed if, while the image is being developed, the light be allowed to enter the dark closet.

We say, then, that *the action of light on iodide of silver is thus purely physical*;* and if in certain processes an image be produced by a chemical action, it is due not to the iodide of silver, but to an organic compound of silver.

But what is the nature of this physical action?

Dr. Hill Norris thinks electricity has something to do with it. M. Testelin, and, before him, M. Poey, think the molecules of iodide of silver have acquired electric polarity, and that, in consequence, the vapours of mercury and the silver become deposited on the affected molecules, in the same way that a light body is attracted by an electrized surface. But these hypotheses are, we think, mere assumption, and do not rest on a single precise experiment. Möser has been more explicit when he put forth the following principle, which was at least founded on neat and clear experiments—that when *one body*

* M. Beuvière remarked that if an iodized silver plate be, by means of a galvanic process, covered with copper, the copper will deposit on the parts affected by light.

has been touched by another one, vapours can make the point of contact visible.

It is supposed, according to this principle, that light can in a determined time give new physical properties to iodide of silver; but how can it be imagined that this time cannot be exceeded without the primitive action being destroyed? This negative action is, moreover, obtained long before the chemical action begins, at least we have no proof of its existence, when already the light has acted too long.

A fact which is not less singular is that certain reducing agents, although more energetic than pyrogallic acid and sulphate of iron, produce no image, although they set free the silver in the nitrate of this metal. Such are, for instance, hypophosphorous and phosphorous acids.

Let us say, then, without reserve, that we do not know the nature of the physical change which takes place by the action of light on iodide of silver. Möser's theory seems the most rational, but does not give a sufficiently exact explanation of the singular phenomena of *solarization* to be strictly true.

If, in the processes where pure iodide of silver is used, or iodide of silver mixed with nitrate of silver, the formation of the image must be attributed to a physical action, it is not so in the processes in which an organic silver compound is in contact with the iodide of silver; and in this case the chemical and physical actions take place together. What proves this, is that the organic silver compounds alone give images which are the more vigorous, as the action of the light has been pushed further, without offering the phenomenon of solarization—at least we have not been able to prove it.* The only silver compounds susceptible of giving images by a physical action are the *iodide, bromide, and chloride of silver*, and each possesses the property of solarization.

Section 2.—Development of the Latent Image.—The points where the sensitive substance has been acted upon by the light condense the vapours of mercury (daguerrotypé), or attract the particles of silver which have been reduced by the action of the developer on the excess of nitrate of silver which covers the film (wet processes).

In the first case, the image is formed by an amalgam of silver, the iodide of silver being subsequently dissolved by the hyposulphite of soda. In the second case, the image seems to be formed of metallic silver—at least, such is the opinion generally entertained. Recent experiments, however, have proved to us that it is not always so.

Images on albumen, gelatine, and waxed-paper, when treated with caustic potash, abandon an organic compound of silver, proves that their composition is complex. The images on collodion do not seem always formed of pure silver, either, as the following experiment seems to prove:—A collodionized and sensitized glass, after having been exposed to the light and developed with *pyrogallic acid*, is well washed, and then dipped in nitric acid. The image dissolves almost entirely; but it may happen that a weak, *scarcely* visible, image remains. This, I observed, is the case principally with old collodion, such as is proper for use in the dry process.

The acid being washed away, the image can even be developed a second time, and a new application of acid leaves always a secondary image.

The examination of the film proves thus:—

1. That the iodide of silver is not altered by the reducing agents.†
2. That the image is formed for the greatest part, if not entirely, of pure silver.
3. A fraction of the image is at times formed by an unknown substance.‡ The fixing agent then dissolving the iodide of silver, leaves in the film pure metallic silver, or silver almost pure, which, by rubbing, takes the metallic aspect.

* We have made numerous experiments on gelatinized, albumenized, and waxed paper, albumenized and gelatinized glass, and collodio-albumen. In all these processes, particularly those on albumen, the iodide of silver has appeared to us as being of no use; and it is sufficient, for instance, to albumenize a glass, and dip it in nitrate of silver, to obtain negatives in the ordinary way (vide Dr. Mouchhoven, the *British Journal of Photography*, for 1862, p. 349).

† Some authors affirm the contrary, and pretend that a film of pure iodide of silver can be developed with pyrogallic acid without the addition of nitrate of silver. The experiments of M. Barreswil and Davanne, Hardwich and ourselves, prove the contrary.

‡ What is this substance? It is soluble in hyposulphite of soda and cyanide of potassium. When dissolved by the latter the image can again be developed weakly. The silver, deposited by a mixture of pyrogallic acid and nitrate of silver, is entirely soluble in nitric acid, thus it does not come from the reducing agent. Moreover, the same thing takes place with sulphate of iron.

PRIZES AT THE PHOTOGRAPHIC EXHIBITION.

ADJUDICATORS' REPORT.

As to four of the medals, we have had no hesitation in fixing upon the names of those best entitled to the honour of the award.

To begin with the Amateurs' Medal. There is a beautiful picture exhibited by the Earl of Caithness; but it is simply a translation, though very faithful and artistic, of an accidental effect of nature. Greater merit is, we think, shown in the series of studies from nature exhibited by Lady Hawarden.

2. In the class of elaborate figure compositions, we can see nothing that can be placed on a level with Robinson's "Bringing Home the May."

3. As for reproductions, Thurston Thompson is *facile princeps* in this Exhibition.

4. Of instantaneous views, the series exhibited by Col. S. Wortley stand alone in their excellence.

So far it has been easy for us to assign the places of honour. In landscape subjects we had much more difficulty, and have not without much hesitation made up our minds as to the rightful claimant of the medal. Messrs. Bedford, Annan, Mudd, Vernon Heath, Dixon Piper, and White have each exhibited pictures of the greatest beauty. If the medal were to be the reward of the best *single* production, we might have found the duty of deciding even more difficult than it is. The medal, however, is to be given as the reward of the greatest general excellence. We find instances in the works of each of the gentlemen already named, either of happy choice of subject, or of skill in the composition of their picture, or of due attention to contrast of light and shade, and to gradation of distance and atmospheric perspective; but we think that we see in Mr. Bedford's works the most complete union of all the qualities which must be united in a good photographic picture.

Taking the same principle of general excellence as our guide in examining the merit of the portraits in the Exhibition, we consider that M. Claudet is entitled to the first place; but we must add that, in delicacy of treatment, nothing can be finer than Mr. Williams's vignette portraits.

The carte de visite portraits of M. Joubert are unsurpassed, we think, by any of that class of pictures. We were also much pleased with the portrait of Thomas Carlisle, by Jeffrey, and with one of the large portraits exhibited by Mr. Voigtlander.

J. DURHAM.

REMEDY FOR CRACKED VARNISH.

BY H. R. NICHOLS.

MANY of your correspondents ask for a method to restore negatives that have become useless by the cracking of the varnish. Having frequently repaired negatives which have suffered that misfortune, I will briefly state the way I manage it; but must state at the same time that a little practice and a little caution is necessary to ensure success.

The apparatus I use is constructed in the following manner:—Procure a tin dish about an inch larger each way than the negative and about two inches deep, with a piece of tin, the size of the plate, or of the largest size of plate used, raised about a quarter of an inch from the bottom; next a rim of wood on the outside to be laid on the top edge, so that a plate of glass, when laid on, fits comparatively air-tight.

Now for manipulating. First, to know the solvent for the cracked varnish proceed thus:—Touch the varnish with alcohol on the end of a glass rod, the plate being slightly warmed at some unimportant part of the negative. If it dissolves, alcohol is the solvent; if not, benzole is probably the solvent of the gum in the varnish. That having been ascertained, we now proceed. Place the injured negative on the raised part of the dish; pour into the lower portion a little

alcohol or benzole, whichever be the solvent, taking care that none of the spirit comes in contact with the varnish surface. Put the glass cover on, and heat the dish by any convenient method—I use a hot tile. The vapour of the spirit will cause the varnish to swell; the cracked portions will unite, at which period remove the glass top, let it cool gradually, and finally varnish again.

2, St. Jude Street.

THE APPLICATION OF PHOTOGRAPHY TO THE MAGIC LANTERN EDUCATIONALLY CONSIDERED.

BY SAMUEL HIGHLEY, F.G.S., &c.*

The bag of oxygen, when wanted, is placed between a pair of pressure boards; half-hundred weights are placed on the upper edge of the boards, and the gas is expelled at any desired amount of pressure.

As the pressure boards, as ordinarily constructed, are of inconvenient size, I have adopted a suggestion of Mr. Madden, the engraver, a gentleman very conversant with philosophical instruments, and make them to fold up, so as to make packages of a more convenient form, the parts, when opened for use, being kept firm by clamps and swivel bars. The arrangement adopted will be readily understood by aid of Figs. 5 and 6.

Fig. 5.

PRESSURE BOARDS OPEN FOR USE.

Fig. 6.

THE SAME FOLDED FOR TRAVELLING.

If both gases are to be used under pressure, the connecting tubes of their respective bags are connected with the pipes of an oxy-hydrogen jet (Fig. 7), whence they are conveyed to a mixing chamber, from which the combined gases are projected upon a lime ball placed at about one-eighth of an inch from the nozzle of the jet. The lime-ball is fixed upon a pin that is turned from time to time; or, if the mixed gases are to be used under greater pressure, the lime-ball is kept in constant rotation by means of clock-work, to prevent holes being burnt in the lime, and the light being thus thrown out of focus of the lenses, or the light being diminished in intensity through the distance between the jet and lime cylinder being increased beyond the proper point. The proper proportion of the oxygen to the hydrogen is regulated by stopcocks till the best effect is produced. If a picture only 10 feet in diameter is to be produced, a very simple arrangement may be employed, a fine jet of oxygen is forced from a bag

* Continued from p. 69.

under moderate pressure through a flame of house gas burning at the end of a brass pipe connected with a flexible tube to the

Fig. 7.

burner of a lamp or other gas supply, Fig. 8, the mixed gases being projected on a lime cylinder, as in the previous arrangement, the incandescent limo being the real source of light.

Fig. 8.

When, however, house gas is not attainable, and the trouble of making pure hydrogen is an objection, a very good light may be obtained by forcing a fine jet of oxygen through a spirit flame on to a limo cylinder, by the arrangement shown in Fig. 9.

Fig. 9.

It should be stated that an argand oil lamp, even if the brilliancy of the light is increased by adding camphor to the oil, is not suitable for photographic views.

If the limo cylinders are to be subjected to a lengthened exposure, under great pressure, they must be made from the best and hardest lime; if under moderate pressure, soft limes may be employed with advantage. Mr. Fryer, of Manchester, has proposed the employment of cylinders, made of two parts of calcined magnesia to one part of sulphate of limo mixed with water, cast in a mould, and then baked, which he states, after careful photometric comparison, gives a light, as compared with ordinary limes, as 54 to 28; as far as I have tried this form of cylinder, I cannot confirm this statement, but much may depend upon the details of preparation.

(To be continued.)

Correspondence.

THE FRENCH PHOTOGRAPHIC EXHIBITION.

SIR,—I notice in last week's NEWS a statement from your foreign correspondent relating to the Photographic Society of Paris, in which, amongst other things, it is announced that an exhibition of photographs will be held there on the

1st of May next. English artists are reminded of this; and some flattering remarks are added with regard to their photographs. Having myself sent several landscape photographs to the last exhibition held by the Paris Society, I feel, with the foregoing announcement before me, that I may be doing some service if I relate what has occurred to me in connection with that exhibition. Let me, however, say that I do this with reluctance, and that I greatly regret the necessity of making this public statement. It will, though, be seen that I have given those who should have furnished the explanation required more than reasonable opportunity for doing so.

The photographs I sent to the Paris Exhibition in 1861 were in six frames, arranged as my exhibition pictures usually are, some containing four subjects, others two. They were forwarded by myself, packed in a case, carriage paid, duly arrived in Paris, were hung, and I possess a catalogue of the Exhibition in which they are mentioned.

As the time approached when, according to the original announcement, the Exhibition should have been closed, I received a letter informing me that it had been determined to keep the Exhibition open for an extended period, at the end of which period, if I desired it, my contributions should be at once returned to me; or, if I did not object to it, they should be retained by the Society until the time came for sending to London the Paris contributions to the International Exhibition, and they should come with them.

I replied by sending the address of my own agent in Paris, and requested that, at the close of the Exhibition, my pictures should be packed up and sent to him. Some time then elapsed, and not hearing anything of them, I wrote to the Secretary of the Society, but had no reply, and I made other applications by letter, but without any result.

Being in Paris at the commencement of this year I determined, if possible, to obtain an explanation of this matter; and having had the good fortune to make the acquaintance of Mr. Ernest Lacan, I asked that gentleman to go with me to the Secretary of the Society.

Perhaps I should mention here that just before going to Paris I heard that Mr. H. P. Robinson had had similar experiences with regard to his contributions to the Paris Exhibition; his case, however, being a stronger one than mine, inasmuch as, beyond the pictures sent for exhibition, he sent a large number of duplicates for sale. But, to continue:—On the 8th ulto., with Mr. Lacan, I called upon the Secretary at the rooms of the Society, who, while admitting that my pictures were received, stated that he was then quite unable to give any explanation as to what had become of them. Mr. H. P. Robinson's contributions he knew nothing about, and stated that he did not even know him as an exhibitor! He would, however, make every possible inquiry, and we were to call the next day. This we did, but nothing had been found out; it was promised me that the inquiry should be continued, and that I should be written to.

Now, sir, I submit that from the 9th of January to the 5th of February is reasonable time for inquiry, but as yet I have had no letter; and, though I can now hardly expect that even this public statement will bring me the information I have hitherto failed to get, it may be useful to those who intend to send pictures to the forthcoming exhibition. I do assure you that I regret that this has happened; had I been treated with even the most ordinary consideration I should have been happy to have continued an exhibitor at Paris.

VERNON HEATH.

43, Piccadilly, February 5th, 1863.

[We regret exceedingly the necessity for publishing the statements above made, or in any way damping the ardour of intending contributors to the French Exhibition; but such circumstances call for explanation or remedy. In Mr. Robinson's case, we believe that not less than ten copies of "Fading Away" were sent and never accounted for. The fact that the prints are now scarce and very valuable renders their loss the more annoying.—Ed.]

Photographic Notes and Queries.

PRIVATE PHOTOGRAPHIC EXHIBITION.

SIR,—I was surprised on reading your article of Friday last, not having met with the disapprobation of other photographic journals or of the local press. Your criticisms in no way daunt me, already nearly all the space is engaged by some of the best artists and well-known publishers; a sufficient proof of the confidence reposed in the projector of the scheme.

By the condition of six postage stamps, the Contributors' Guide is likely to be desired only by those wishing to forward specimens.

The guinea intended to be used for purchasing prizes and procuring judges does not refer to *all* exhibitors, but to those only who, after fifteen clear days' inspection of the works of other competitors, may deem it expedient to invest their money. Of the gentlemen kind enough to act as umpires, some may not be able to do so without considerable loss of time, not to speak of travelling expenses; it is therefore but natural that those to whom the advantages accrue should provide for such contingencies.

Should the above plan fail in making the exhibition defray its own expenses, four gentlemen of property and respectability, who take an interest in the undertaking, are pledged to me as manager to bear an equal share of the liabilities. These gentlemen's names I am not at liberty to set forth except when their financial connection with the exhibition may render it necessary. One important item you have not laid before your readers, many of whom may not have had an opportunity of seeing my circular, viz., the packing, arrangement and repacking of all goods sent. This, together with catalogues and other incidental expenses, will be no slight matter, considering that I run the risk of that failure you have so kindly prognosticated.

Supposing the whole proceeding to be a "blunder," on whom will the responsibility devolve? Not on the exhibitors, they are merely invited to accept an opportunity of displaying their productions, but on the daring individual, the originator of an enterprise, who, though "a private unknown individual," will be able to carry out the entire project to the very letter.

The insertion of this in your next number will greatly oblige, sir, your obedient servants,

A. G. GRANT, *Manager*.
G. LASSALL, *Secretary*.

TO PREVENT THE SILVER BATH BECOMING DISCOLOURED.

SIR,—I have much pleasure in being able to give a method for preventing the silver bath turning colour after using albumenized paper.

Instead of dissolving the silver in distilled water, use common hard water that has been *boiled* in an ordinary kettle, and then let it get quite cold before dissolving the silver.

I tried the plan of using common water before boiling, but I found such an objectionable deposit in the bath, so gave it up.

There is a slight deposit by using my method, which is scarcely worth mentioning, and which had better remain in the bottle.

I have had this plan in use for the last two months, and my bath now is as white and clear as when first made.—I am, sir, yours, &c.

Bristol, Feb. 6, 1863.

WM. CLARK.

HOW TO KEEP GUN COTTON.

DEAR SIR,—The following incident, which occurred to me the other day, may, perhaps, be interesting to some of your readers, as showing the danger of keeping pyroxyline closely stoppered. I have had some pyroxyline by me for about a year, made from paper; it has been in a stoppered bottle, cemented, and capped with bladder and leather. I happened to take it from the cupboard in which it has been kept, and observed the pyroxyline, in the upper part of the bottle, to be slightly tinged with yellow, so thought it advisable to open it, knowing that pyroxyline keeps much better when exposed to the air. I took off the leather and bladder caps, and removed the cement, when the stopper flew out with a loud report, large quantities of nitrous fumes were emitted, the bottle was cracked, and quite hot at the upper part. I have always made my own pyroxyline in India, and have found it keep perfectly well, simply wrapped in paper, and placed in a cupboard, or on

a shelf. I have pyroxyline, which was made three years ago, and has been kept in this way; it is in the same condition as when it was made. I have received samples of pyroxyline in India, which were sent out to me by different firms in England, and there were always nitrous fumes in the bottle—sometimes plentiful, sometimes in small quantity. I have kept the same pyroxyline for a considerable time afterwards, wrapped in paper, and it has not suffered any further decomposition. I feel sure that pyroxyline may be kept for any time if exposed to the air. I have kept it myself for three years in this way; if it is hermetically sealed, it will begin to decompose in less than six months; much, doubtless, depends on the thorough washing of the pyroxyline. The samples I have alluded to I believe to have been perfectly washed; but I am confident that the above remarks will apply to any cotton, however well washed.—I remain, yours faithfully,

N. L. NOVERRE.

25, South Street, Park Lane, Feb. 8, 1863.

[Under some circumstances pyroxyline will undergo change with keeping, however stored; but it should never be kept airtight. We always keep it in paper parcels, or in a wide jar with loose paper cover, and have kept it for months and years without injury.—Ed.]

SUBSTITUTES FOR PRINTING FRAMES.

DEAR SIR,—Having some time since invented substitutes for printing-frames, which I find to answer perfectly, and at the same time do away with the slightest risk of breaking a negative, whilst the cost of them is trifling. I send you a description of them for the benefit of your readers. The principle in all sizes is the same, but I will describe the frame for a $\frac{1}{4}$ -plate negative. I first get a 5×4 plate, and having measured the right length across it, when at full tension, of a very wide piece of elastic; cut it off, and sew two hooks to each end of it. I do the same with two other pieces. I then take a $\frac{1}{4}$ -plate and cut it in two with a diamond. The frame is now complete, and is thus made use of;—The $\frac{1}{4}$ -plate negative is placed on the 5×4 plate, then the sensitive paper, and pads of soft paper, &c., cut exactly $3\frac{1}{4} \times 4\frac{1}{4}$ then the half pieces of quarter plate, and then the elastics hooked over all onto the 5×4 one, over each half, and one over the joining (but this is not essential). If properly made there is abundance of pressure, no risk of breakage, and they are easier to open for inspection than the ordinary frames.—Yours most respectfully,

D. WARD.

Manchester, Feb. 3, 1863.

GUTTA-PERCHA PAPER.

DEAR SIR,—It seems that there is nothing new in the world. Scarcely is an improvement suggested, or something new introduced when a somebody appears revealing that it has been done in such and such places, and even in our neighbourhood. Now there is only one question that arises from such assertions: if paper has been prepared by Mr. So-and-so, &c., and it proves valuable, why was it not made public? What is the use speaking now about filthy lucre, sordid gain? For my part I must confess I never heard of any other paper but albumenized and plain, and lastly of Mr. Cooper's, to whom photographers owe many thanks. Mr. Sutton's paper will prove a great boon when he has overcome all difficulties. The preparation of the waterproof solution is even not very easy; it may do for waterproofing shoes but not paper; but even when it has been done properly, there are other things which most leak out in order to obtain a fit paper for photography. I take the liberty of enclosing two *cartes de visite* printed on my gutta-percha paper; they were done by Mr. Hogg, of Kendal, and you will see his remarks. The paper sent to him was Causton's, which I had in possession for the last seven years. He speaks of the slow printing, which I account for the not having known the strength of his bath. I will feel obliged if you point out the defects, and it will guide me how to improve. I must not omit to state that I have prints which were only washed for five minutes, and are now for four weeks exposed to light, and I do not perceive any change. I expect some paper from London, and by your permission I will send you some prepared paper; and if you should find it good, I shall feel glad that my experiments have not been in vain. As customary, begging you to pardon my bad English, I remain yours respectfully,

ALEX. ARNSTEIN.

Ambleside, January 27, 1863.

[The prints received are a trifle flat and inky in tone; but that would doubtless be overcome by practice.—Ed.]

Talk in the Studio.

SOIREE OF THE PHOTOGRAPHIC SOCIETY.—The soiree of the London Photographic Society will be held on the evening of Friday the 20th. inst., in the Suffolk Street Gallery, where the exhibition is now held.

NEW EXHIBITION.—We understand that in consequence of the flattering manner in which Mr. Highley's paper on "The Application of Photography to the Magic Lantern" was received by the members of the Society of Arts, he proposes opening a public evening exhibition of his science and art photographs, at the Burlington Gallery, 191, Piccadilly, on Wednesday next.

"COAGULATING" THE SURFACE OF ALBUMENIZED PAPER.—Mr. A. Wood, of Brunswick Street, Edinburgh, informs us that he has found an easy and efficient method of rendering insoluble, or "coagulating," as it is improperly termed, the dried albumen on albumenized paper. He says:—"The means I employ is a pipe leading from a steam boiler into a receiver—the steam is admitted or shut off by a cock at the receiver. I enclose the paper in a box having holes in the sides, and covered with blotting paper and allow it to remain five or six minutes. When taken out it is only slightly damp, and completely changed in appearance, the surface being much more brilliant and beautiful." Mr. Wood has sent us some samples in which the surface is rendered quite insoluble. He states that with a 40-grain bath very brilliant results are obtained. We consider the subject very important, and shall take an early opportunity of giving it more attention.

To Correspondents.

COLOURED GLASS.—EXCELSIOR forwards a specimen of yellow glass for examination. It is coloured throughout, and is of rather a light colour.

In the spectroscopic it is seen to be tolerably opaque to the chemical rays, but a few of the blue struggle through, which would render it unsafe in bright light. To Excelsior's further questions we may state that common water may be used for making an iron developer, but if it contain any large proportion of chlorides, carbonates, &c., it may cause some trouble by throwing down the free nitrate on the plate as a chloride or carbonate, instead of allowing it to give density to the negative. The chloride of gold to which you refer will doubtless answer for a toning solution after the Abbé La Borde's formula.

G. F. S. forwards some flashed orange glass. It is of the best quality, and perfectly trustworthy as a medium for glazing the dark room.

BRADFORD.—Dr. Hill Norris's plates will keep after a packet has been opened, but not so well as before. It is important to keep dry plates air-tight as well as protected from light. Moisture and vapours present in the atmosphere are often injurious to dry plates.

R. W.—The No. 1 Triple is not intended for, nor well suited for card portraiture; nor is it suitable for stereoscopic work. It is of a focus too long for such work. If you require a lens for both these purposes, a quarter-plate or No. 1 B of the maker you name will meet your wants.

A.—Two grains of iodide of potassium are sufficient for a pint of nitrate bath. You have added too much, and probably, from the sandiness you describe, supersaturated your bath. The two grains in the formula to which you refer doubtless are meant for the whole bath, not for each ounce of solution. Dilute your bath with an equal bulk of distilled water; let it stand all night, then filter, and add sufficient nitrate of silver to make it the proper strength. 2. The path of insensitiveness to which you refer may arise from the film having got dry at that end before immersion, or from a variety of causes which we cannot with certainty specify without seeing a plate.

INQUIRE.—We do not know of any plan of drying prints except hanging them up or spreading them out. If they are blotted off with clean blotting paper, to remove the surface moisture, they soon dry, however arranged.

ANXIOUS.—If, when using pure albumen, it sink into the paper, drying dull and irregularly, the fault is in the paper, which is too absorbent, and probably new. Untilage has thoroughly hardened the surface of paper, the size is very apt to become partially dissolved; this will cause the albumen to sink partially in and dry with a dull, irregular surface, disfigured with curtains. The only way to meet this difficulty when the tendency exists, is to float the paper for a very short time, not more than a few seconds, or indeed not more than on and off the albumen, taking care to add no ammonia to the latter as sometimes recommended, and to have the room at a sufficiently high temperature, not lower than 70° Fah. There is no "secret dodge" in successful albumenizing, except the knowledge of conditions arising from experience, and good manipulation. We do not know of any book which gives any special details of this subject.

AN ANATEUR.—Mr. Sutton's patent is for a method of preparing paper with india-rubber previous to albumenizing. The paper is to be had of Messrs. Ordish and Lampray, Paternoster Row. The resinized paper process is due to Mr. Cooper; paper by his formula is prepared by Messrs. Francis and Co., Islington. We have not tried the rose-tinted paper.

H. S.—It somewhat depends upon the quality and form of your quarter-plate lens, as to whether it is well suited for enlarging at all; but there is no especial limit to the extent of enlarging to which it may be put. A triple lens is the most suitable for enlarging. 2. Considerable difference of opinion prevails amongst authorities as to whether the presence of some free nitrate increases the sensitiveness of a dry plate. The general opinion is that it does; but Dr. Hill Norris, one of the best authorities on the subject, says it does not, and that his instantaneous dry plates have no free nitrate present.

P. SKEOLAN.—A form provided at the Register's Office at Stationer's Hall must be filled up with the necessary particulars and left at Stationer's Hall, together with one shilling for each photograph to be registered. You will find full particulars in the number for December 26th last, and some preceding numbers there referred to. Also in our ALMANAC.

LENOIR.—The tone and general character of the print are good. The dark patches doubtless arise from the varnishing. We have noticed sometimes that negatives intensified with bichloride of mercury when varnished with a rather thin varnish, especially if the plate be made a little too hot, are spoiled by the varnish passing through the film made porous with the mercury, and settling in small patches between the film and the glass. In all these patches the negatives become more transparent, and the patches print blacker, as in your case.

M. D.—Mr. Osborne has not published any specific work on photolithography. He delivered a lecture on the subject in Melbourne, which was published in the English photographic journals, and also in a small, separate pamphlet. In this lecture, contained a sketch of various photolithographic processes, which you will find on pp. 374 and 388 of our fourth volume. Various articles on the subject, historical and practical, have recently appeared in our pages. A work recently issued by M. Poitevin, entitled "A History of Printing without Salts of Silver," also contains much information on the subject.

S. R.—Your figures are lighted with too much diffused and too little direct light; and you have decidedly too much front light. There is no appearance in your prints of want of bromide. 2. Of the two makers of lenses you name, the latter is the best.

ENIGMA.—Dallmeyer's new stereo lens is not intended for card portraiture, and with full aperture it will not be likely to answer the purpose satisfactorily. To obtain good definition with it over the whole of a standing figure a small stop will be required. For rapid work in card portraiture you must procure a lens especially constructed for the purpose. 2. A solution of iodine is sometimes used in intensifying before fixing, prior to the application pyro and silver. We will make use of your other communication, for which accept our thanks.

X. Y. Z.—We do not know anything of the qualities of the first lens regarding which you inquire; but have seen excellent work with that of the second maker. 2. A great many qualities go to constitute rapidity and excellence in a lens. The conditions you name, large diameter, short focus, and pure colourless glass, are important in securing rapidity, but there are others not less important, which the skilled optician must consider. Every varying density in the glass, for instance, will require some modification in the figure of the lenses to meet the case. There are many such points, which are the business of the optician, and he who best understands his business produces the best instruments.

J. W. S.—Our pages have almost teemed with recipes for toning baths during the last few years. That with the acetate of soda is as simple as any. Here it is again: chloride of gold, 1 grain; acetate of soda, 30 grains; distilled water, 6 ounces; mix 24 hours before use. With skilful manipulation, 1 grain of gold will tone from 1 to 2 sheets of paper. A deep tone depends on a good negative, strong nitrate bath, good paper, deep printing, and sufficient toning.

A. B. D.—If you send us a specimen of the defect we shall be able to form a better opinion of the cause.

JOSEPH FORD.—We will take an early opportunity of noticing your slides. 2. You may copy engravings in which no copyright exists, but you may not photograph copyright engravings.

G. STANHAM.—Some samples of chloride of gold are adulterated, but as a general principle, the adulteration is not of an injurious kind beyond robbing the purchaser of a portion of the gold he pays for. A common adulteration is chloride of sodium. Any solution made with such gold will be weaker than intended in proportion to the amount of adulteration present. We have no means of saying that the samples sold by any manufacturer are better or worse than others. 2. If you make an ammonio-nitrate bath, make it according to the formula we have given several times; but if you are uncertain of your manipulation make a plain 70-grain bath and use it as nearly neutral as possible, or very faintly acid with nitric acid.

J. M. LEAHY.—In the case referred to, Mr. Barrett used the Stanhope lens almost in contact with the portrait lens, and your conjecture that the latter in such played an unimportant part in the matter is correct. The greater power of the former would almost ignore the action of the portrait lens. The most satisfactory lens for the purpose is a microscopic object glass of about 13 inch power. You might use one of the lenses you name as a condenser. Your letter, unfortunately, got mislaid, or it would have had attention sooner.

WILLIAM COCK, Rio de Janeiro.—This gentleman is requested to send his address to Mr. Wall, who, having mislaid his first letter, was unable to send the desired information. A second note received since did not give the address.

Several correspondents in our next.

FUMING ALBUMENIZED PAPER WITH AMMONIA.

Palmar qui meruit ferat, is a good motto at all times, and is frequently of especial application in an art-science like photography, which owes its rapid progress and present proud position to the ability and ungrudging liberality with which so many of its votaries have given their discoveries, small and great, to the general stock. It is not unfrequently a matter of some difficulty to trace the exact origin of many new ideas or improvements, as they often appear to spring up simultaneously in different quarters. Here is one of those cases in which a misunderstanding has arisen regarding a process, of which we scarcely know yet whether it is to become important and popular, or to drop into "the limbo of vanities" and be forgotten. The worthy Editor of the *American Journal of Photography* has received some unintentional injustice at our hands, in not receiving the amount of credit due in connection with the process of forming ammoniac-nitrate of silver on albumenized paper by fuming. The case stands thus:—

Some time last Autumn, Professor Emerson communicated to us in confidence the process in question, for our own use, and not for publication, as the originator, Mr. H. T. Anthony of New York, did not wish it published then. We had a dim impression at the time that we had met with the idea before, but could not quite recall it. We had respect to the confidence reposed in us, and did not publish any allusion to the matter. A few weeks afterwards, Mr. Penny, of Cheltenham, wrote to us a letter for publication, stating that such an idea had occurred to him, and that he had tried it with success. We could not of course, in fairness to our American friends, publish this letter without alluding to the fact, that the process was used by some gentlemen in America, whilst Mr. Penny's letter announcing his independent discovery, absolved us from secrecy. We therefore frankly stated the circumstances, endeavouring to do justice to Mr. Penny, to our readers, and to Professor Emerson. A few weeks afterwards we received from that gentleman a letter, in which, amongst other things, he asked, as Mr. Anthony's secret discovery had got into print, would we give him due credit. It was really Mr. Penny's discovery which had got into print, with a courteous allusion to the prior use of the process in America; but in deference to a gentleman who possessed our esteem, we made the desired announcement. In reference to this, a recent *American Journal* contains the following remarks:—

— *What does it mean?* The editor of the *News* (December 12), announcing the receipt of a letter from Professor E. Emerson, concerning matters photographic in America, says, "In the first place we are desired to place on record that it is to Mr. Henry T. Anthony, of the well-known firm of E. and H. T. Anthony, photographers are indebted for the discovery of the value of ammonia fumes in printing on albumenized paper. . . . Professor Emerson communicated to us the process in confidence."

Some further remarks follow in reference to Mr. Sellers,

who, having seen the announcement first referred to in our pages, wrote to a contemporary promising particulars, and adding that without doubt the discovery was due to Mr. Anthony. The Editor then further remarks:—

How strangely sound the expressions we have underscored! The fuming process was published in this journal, for plain paper, by Mr. Campbell, of Jersey City, vol. i. p. 57, and for albumenized paper by the editor, vol. iv. p. 500. Mr. H. T. Anthony is not a subscriber to this journal, and therefore may be excused by some for being far behind the times. Mr. Sellers without doubt has overlooked the articles in this journal, and will make the proper explanations. Professor Emerson has informed us that he was not aware of the publication of the process in this journal, not having been at the time a subscriber, and that his information came only from Mr. Anthony. On the supposition that the claim of Mr. Anthony is just, what a funny thing it is that we must get the news not direct, but by way of Philadelphia and England! From 501 Broadway to Canal Street is only a good stone's throw; but by the other route it is 6,000 miles! We have more to say on this subject. We only add now that we never heard the name of Mr. Anthony connected with the fuming process till the receipt of the English journals above quoted from.

To whom the discovery was really due we cannot state. Mr. Anthony, it is quite possible, may have discovered it and used it years ago. But to the *American Journal* is unquestionably due the merit of first publication. We stated that when Professor Emerson first mentioned the matter we had a dim conviction that we had heard the suggestion before. If our readers will turn to p. 213 of our last volume, May 2nd, 1862, they will find an article from the *American Journal* in which the suggestion is made. The precise fact had escaped our memory, an uncertain impression only remaining when the matter was again brought under our attention. It is only just now to recall the fact.

About the exact value of this process we are less certain; and at present wait for evidence. It stands on our notebook, amongst many more processes, to be tested and verified when time and circumstances permit. Mr. Penny, of Cheltenham,* exhibits, in the present exhibition, some illustrations, from which it appears that a 40-grain silver bath with the fuming gives equally good results as a 60-grain bath without it. On the other hand, we have had some communications from an able photographer, from whom we learn that in his hands the fuming was a failure. No accession of sensitiveness was gained, and the prints were flat, poor, and grey, much inferior in brilliancy to prints from the same paper, silver bath, and negative, without the use of ammonia.

Whilst referring to the above subject, we may take occasion to correct another misapprehension in the mind of our American contemporary. In another article he complains a little of the "harsh criticism" on American inventions of English photographic journals; and states that perhaps

* A contemporary, by the way, has overlooked the fact that the use of ammonia fumes in printing is an independent discovery by Mr. Penny, and refers to his specimens as the result of Mr. Anthony's suggestion.—Ed. P. N.

they receive "some tinge of the present prevailing prejudice against almost everything American." We feel concerned to disabuse our American friends from any such notion. We are profoundly thankful that the charge of a scientific journal absolves us from the duty of dealing in any way with the complicated difficulties which now harass the great American nation, and from which we wish them a speedy and satisfactory deliverance. But, as regards American photography and photographers, we can assure all concerned, that they are held in very high respect, indeed, in this country. The time was indeed, when, as a whole, American photography was immeasurably ahead of that of any other country. We have seen in the galleries in New York, Philadelphia, Baltimore, Washington, and other American cities, Daguerreotypes which were, beyond all comparison, superior to anything we have seen in this country, or in the cities of continental Europe. In the production of photographs on paper, this superiority does not, we believe, exist, but it is rather because of the advancement on this side of the Atlantic, than of any inferiority either in knowledge or executive skill in our American friends, whose productions are still inferior to none in the world, and whose enterprise, ingenuity, and skill, have largely contributed to the general advancement of the art.

THE PHOTOGRAPHIC EXHIBITION.

FOURTH NOTICE.

THE landscapes in the Exhibition, as we are told by the adjudicators of the medals, present the greatest equality of excellence. It is perfectly true that in no previous exhibition have we noticed such a large number of thoroughly good landscape photographs. Whilst, however, there is so much uniformity of excellence, we have never noticed an occasion in which the distinctive characteristics, or "manner," of each artist was more broadly marked.

Amongst the best as well as largest of the landscapes exhibited, are those of Mr. Annan, of Glasgow. In all his pictures there is much artistic feeling, and they are characterised by an amount of massiveness, vigour, and breadth, very unusual in photographs. The relief, distance, and atmosphere are also exceedingly satisfactory. Mr. Annan avoids the enormity of white skies; clouds of an atmospheric tint is present in each of his pictures, admirably preserving harmony and breadth. Mr. Annan usually prints from separate cloud negatives, and is very successful in results. An interesting illustration of a favourite dictum of ours, to the effect that results depend on the man more than the method, is illustrated in Mr. Annan's contributions. We have, amongst his pictures, tannin and wet collodion, with a singular identity of characteristics. His "Loch Ranza" (No. 258), a picture about 16 by 12, from a tannin negative, and the "Last Stooks of Harvest" (No. 152), another charming picture of similar size, are in no sense, photographic or otherwise, inferior to "Kelvin Grove" (No. 222), "Aberfoyle" (No. 182), nor "Head Waters of the Frith" (No. 257); all of which are from wet collodion negatives. The "Muirland sac Dreary" (No. 145), and "Ben Venue from Loch Ackray" (No. 108), are also two charming pictures from tannin negatives. The three very admirable reproductions produced for the Glasgow Art Union, are also exhibited by Mr. Annan, as well as some other good pictures.

Entirely differing in style from those we have just noticed, and possessing excellence of altogether another order, are the landscapes of Mr. Vernon Heath. If the last were characterized with massiveness, these are distinguished by wonderful delicacy of feeling and manipulation. These qualities have always distinguished Mr. Heath's pictures, and in this year's pictures they are present in a more than usual degree; we have very rarely seen photographs uniting so completely force and delicacy, brilliancy and softness. A large number of Mr. Heath's pictures have been taken in

the grounds of Lord Ashburton, at The Grange, in Hampshire. One frame of four pictures especially pleases us. (No. 127). The two lower pictures in this frame are as perfect as we have ever seen photographs. The exquisitely defined distance, with its reflections in the transparent water, seems rather a dream of fairyland than a photographic transcript of actual nature. No. 133, "By the Lake," is another specimen of this marvellous delicacy of treatment. The chief feature in the picture is a silver cedar of rare magnificence; and although rendered in the monochrome of the photograph, it seems modelled in frosted silver. "A Study of Ferns" (No. 143), is such a bit of foreground, the rendering of which will delight the heart of Brett or Linnell. Several of the views of Windsor are magnificent pictures. Mr. Heath has introduced natural clouds into all his pictures this year, from separate negatives, whereby an immense gain in unity, harmony, breadth, and atmosphere is obtained. His pictures have given rise to some discussion, from the fact that the clouds in many of the pictures are printed from different parts of one negative. We feel so strongly the value of the sky in making a picture, that for such a purpose we would pardon a fault more venial than this. Variety of effect is doubtless desirable, but if the clouds are obtained under the same conditions of light, and are used so as to aid the composition, and be in harmony with the landscape, we are disposed to think that the repeated and judicious use of the same negative is quite permissible.

Mr. Bedford exhibits a number of his Eastern views, which we have already noticed, and a few other, of landscapes and interiors in this country. All his pictures have gained immensely by the introduction of skies. Perfect as the photography always was, and characterized as it was by artistic feeling, the harmony of some of his pictures was in former years impaired by the white paper sky. Now we find always a tint or clouds. Mr. Bedford adopts the method perfectly successful in his hands, of painting clouds occasionally at the back of his negatives. In less skilful hands such an attempt would fail in producing good results. But here we never dream of questioning its legitimacy, and we think it a noteworthy circumstance that pictures so treated secured the prize for landscape excellence. It would be difficult to select from these contributions any one excelling the whole, and all are pre-eminently characterized by softness, completeness, and harmony.

Mr. Henry White, amongst the earliest artistic landscape photographers, still preserves his position. Every picture is chosen with an artist's eye, and the photography is in all cases good; although in one or two instances the harmony is disturbed by a white sky.

Mr. J. Spode, who generally sends some good pictures, has some very fine landscapes indeed at this exhibition. His "Harlech Castle" (No. 256) is a most charming photograph.

Mr. Dixon Piper contributes some very excellent photographs, many of which we have, however, seen before. His "View near Rokeby" (No. 75), is especially fine.

Mr. G. S. Penny exhibits some very fine pictures from negatives taken on plates prepared with tannin and malt. "Tintern Abbey" (No. 170), is a very fine picture, with some well managed clouds. "On the Wye, Chepstow" (No. 362), is also a charming photograph.

Mr. Baynham Jones exhibits some good tannin pictures, one of which is hung near the fireplace, but not numbered, and is worthy of remark from its similarity to the pictures by the panoramic lens in shape and size. It is apparently about eight inches long and three and a half deep, and is taken with a Dallmeyer No. 1 triple lens. The effect for many subjects is very good.

Sir A. K. Macdonald exhibits a view of "Antis Cove, near Torquay" (No. 269), which is very fine, and possesses some fine natural clouds, apparently produced at the same time as the bold foreground of sea and rock.

A picture by Mr. A. S. Fisk deserves attention for the same reason. It is a view of the "London Extension Rail-

way Bridge, Battersea," and besides being a good picture, possesses some fine natural clouds.

Mr. F. C. Earl contributes some of his large views of "Witley Court," which have been exhibited before, but now have the effect of new and better pictures by having good skies printed in. Some large interiors of the same building are remarkable, as illustrating the depth of focus yielded by the triple lens, and as showing the advantages of a coating of honey with wet plates, where long exposure is necessary. These, notwithstanding the large size of the plates, are very brilliant, perfect, and clear.

Mr. Stephen Thompson's "Durham Cathedral from the Wear" (No. 176), is a fine picture, as are also some of the views of the "Abbey, Lindisfarne."

There are some other landscapes more or less worthy of notice, for which we have not space at present.

PRINTING DIFFICULTIES.

BY A PHOTOGRAPHER'S ASSISTANT.

THE necessity for an observance of a definite and more clearly understood rule in chlorodising albumen, is strikingly perceptible in the samples of slightly albumenized papers now in the market, the ever varying colour yielded by those papers has hitherto been considered the results of the acid or alkaline sizing employed in their manufacture. I think a little observation would convince the most sceptical that the sizing has but little, if anything, to do with it, that, in fact, the changes are caused by the changing influence of the light employed in reducing the silver salts; if the sensitive surface of a slightly albumenized surface is exposed to a dull light, the results are directly opposed to those observed in the highly albumenized samples; the former will yield prints of a bold blue tone, because the excess of chloride salt is most sensitive to light, and for this reason will reduce most rapidly, so that the print has attained the necessary depth ere the albuminate of silver has been acted upon to any extent. This extra sensibility is, doubtless, by some photographers considered an advantage; I am inclined to believe it is not, for whilst the chloride salt is the most unstable, and consequently requires deeper printing, the absence of the necessary proportion of the albuminate is liable to mislead us, however careful we may be in conducting toning operations, for this deep violet colour will oftentimes cause the prints to be removed from the toning bath ere it has gone the necessary depth to resist the reddening influence of the fixing solution.

Do we require proofs to convince us that the albuminate of silver remains unreduced in a dull light? If sceptics to this doctrine exist, let them place their printing frames in a shaded corner, if the paper employed be of coarse texture, and slightly albumenized, except the quantity of chloride salt is unusually small, the print will assume a blue or violet tone. Now let the frame be removed, and exposed to a brighter light, and speedily this cold tint will change to a bright and warmer hue. Why? because a reduction of the albuminate of silver has been effected, and a satisfactory print is the result. Now, had a more judicious salting been observed, the quantity of chloride of silver present would not of itself have been sufficient to give the necessary depth to the picture, and consequently the assistance of the albuminate would be needed, to produce the necessary depth of printing, or at all events, the print would contain a larger portion of the last named salt, the reducing action would move slower, but the improved results would make amends for loss of time.

In highly albumenized paper, the printing proceeds too slowly, because the albuminate is in too great an excess; whilst the slighter coated samples, in a dull light, print too rapidly, because the excess is in favour of the chloride salts. Hence we see the necessity of a series of well conducted experiments in this direction, to determine the proportion one should bear to the other, in order that the best results

may be arrived at. Some may here feel disposed to inquire the reason why lightly albumenized surfaces should contain a larger proportion of the chloride of silver than the highly-coated samples? Simply for this reason—the greater the fluidity of the albumen, the stronger its penetrative and diffusive power, and it follows that it extends itself over a larger surface than the thicker fluid can possibly do; it permeates the interstices of the paper, thus increasing largely the area of surface, and its every atom of chlorine is brought into immediate contact with the silver; and this is sufficient of itself to guide us in operations of sensitizing. A bath too strong is oftentimes an unsuspected cause of failure; the paper becomes saturated, and bears in its surface even to the closing of its pores a large amount of free nitrate. When this occurs the print bears a mealy appearance when removed from the printing frame. The chloride and albumen salts have been reduced, but the nitrate of silver continues in an unreduced condition; the finely-divided atoms extended over the entire surface of the picture, giving it the appearance of a flour bag having been shaken upon it.

And now for a word or two concerning the strength of sensitizing solution required. I stated in the early part of this paper that an 85-grain solution was required for highly-coated papers. With the slightly albumenized samples no advantage is gained by using a bath too strong; from 60 to 65 grains per ounce, is ample and most safe in working. To go beyond that quantity renders it necessary to float but a short time, say from one to three minutes. This method may do for the thoughtful printer that studies the requirements of his paper; but for the amateur, whose experience is small, it is dangerous, as he either nervously withdraws the paper too soon, or he leaves it too long, and thus engenders mealiness with the strength above named. A little over-floating makes no difference in results.

And now concerning water employed for washing, I would counsel all who value satisfactory results in their printing operations, avoid rain water that has been deposited in a tank; use spring, well, or any other clean waters that are fresh, but avoid rain water, however tempting its appearance, insidious organic poison is lurking in the crystal goblet which will insinuate itself into the affections of the silver the surface of your paper contains; and then with weary dejectedness you will watch the changeless prints as they float on the placid bosom of your toning solution, and as the old brass clock strikes at the expiration of each fleeting hour, the chloride of gold solution will again and again be added, moving the prints—yes, moving them more swiftly towards the mealy destruction the organic poison from the first had consigned them. If the printer would avoid this evil, and any trace of it crosses his path, let him suspect his water. Change it for another sample; for evils created by water are the easiest to be rid of; and now, in conclusion, I would observe my object in writing is to endeavour to rid the art of photography from empiricism; I wish to see its principles thoroughly understood; in a word, I wish every practitioner of our art to know the causes of success as well as the reasons of failures, and I see no reason why a space in the PHOTOGRAPHIC NEWS should not be set apart for discussing the causes of success in every branch of photographic art; if this plan was adopted, and photographers would assist the Editor in his arduous duties, our art would, I am convinced, be greatly improved by the practice.

ON IRON DEVELOPING SOLUTIONS.

BY M. MC A. GAUDIN.

I HAVE undertaken, as promised, a fresh examination of the proto-salts of iron, other than the proto-sulphate, for the development of negatives. This time I have had a certain success, which I hasten to communicate to my readers.

The salts of iron, at the minimum of oxydation, possess of themselves alone every degree of reducing energy which we encounter in the series of organic substances with a carbon

base, and each of these salts exhibits behaviour which depends on the nature of its acid.

The proto-sulphate, so much used at the present day, is distinguished by the fineness of the details it gives, and the sensitiveness it produces, but it rarely gives sufficient intensity which necessitates strengthening. The proto-nitrate and the proto-acetate give at once pictures of the greatest intensity; but the half-tones are often defective; the difficulty consists in their giving a sensitiveness as great as that inherent to the employment of proto-sulphate of iron.

In order to avoid their preparation by double decomposition, which is always tedious, expensive, and irksome, I have attempted to prepare these salts in a direct way with iron and the acids; and I have been very successful.

To prepare proto-nitrate of iron, it suffices to digest during four and twenty hours iron in a fine state of division, in nitric acid, diluted with *ten parts of weaker*. It thus forms, after being shaken from time to time, an olive green liquid when viewed by reflected light, and deep red by refracted light. This is the proto-nitrate of iron ready for use.

To prepare the proto-acetate, according to the same process, we take the concentrated acetic acid of commerce, and promote the reaction by a gentle heat which manifests its action by the disengagement of an infinity of microscopic bubbles, due to the decomposition of the water. This action is very slow, but little by little the liquid assumes a wine-red tint, and at last becomes as red as blood.

While these salts are forming, it is necessary to test them, in order to stop the reaction at the opportune moment. To this end we soak some pieces of ordinary white paper in the solution of nitrate of silver used for sensitizing, and after having submitted them to the action of light until they just begin to turn yellow, we place them near the salts in course of preparation, to make them serve as tests, which is done by touching these papers with a glass rod dipped into the solution. At first, the salt in which acid predominates discolours the paper, especially the proto-nitrate; but gradually the salt becomes a reducing agent, and makes a black mark on the paper. When the blackening appears very distinctly, the salt has attained its maximum of reducing power, but it may be too strong. To make sure of this, it must be submitted to a reverse test. After having diluted the salt with four or five parts of water, as if it were to be employed for development, we take a glass rod moistened with it, and touch a piece of the silvered paper that has not been exposed to light. In this case, the paper must not become coloured in less than five or six minutes. If a black colour appears immediately, which often occurs with the proto-acetate, the salt must be aerated, or some drops of nitric acid added, to oxygenate it, for, in fact, as I have many times repeated, the efficacious salts of iron are the oxydule salts, and not those of the protoxide. The instantaneous blackening of the nitrate of silver bath, which I have before attributed to an organic matter derived from the acetic acid, has no other cause; in every case we can remove this impediment by a gradual addition of nitric acid, followed by aeration.

The proto-sulphate and the proto-acetate of iron have a tendency to make the developing solution muddy during the developing, which the proto-nitrate does not. I fully believe that this is due to a double decomposition ultimately produced: there is the formation of insoluble sulphate and acetate of silver, which are reduced to the nascent state, while between the nitrates this phenomenon does not occur.

The essential characteristics of the proto-nitrate are, the slowness of its reduction, the constant limpidity of the liquid, and the pushing to an intense black, which is permanent; but, on the other hand, the most delicate half tones are wholly wanting; and this is just what remains to be attained. For example, after having sensitized a small plate and having placed at its back a piece of red or yellow glass, if we expose the plate to light for a few seconds, and then develop it, the profile of the coloured glass will detach itself perfectly pure and clear upon a black ground of the greatest intensity, and in this clear portion, at the end of ten minutes, the iodide

of silver will have become insensitive to light, for we may pour upon it in the open air some nitrate of silver mixed with proto-nitrate of iron, and double the intensity of the black without sensibly dimming the light portion.

While we cannot obtain the half-tones by development with proto-nitrate of iron; this salt is found, by the same fact, superior to all others for certain purposes; for example, the negative of an engraving is composed of lines or points, more or less distant from each other, *but all of the same intensity*; the blacks cut sharply on the whites. With the proto-nitrate of iron, the blacks will not send sufficient light to impress, while the whites will work themselves upon the negative in a black of an intensity proportionate to the duration of the exposure. This does not take place with the proto-sulphate and pyrogallic acid, which seldom gives skies fit for printing, without some additional coating.

The proto-acetate is intermediate between the proto-sulphate and the proto-nitrate; it gives a bistre tint of the greatest beauty, the intensity of which is exactly proportionate to the duration of the exposure; but it, at the same time, gives half-tones; and from the day when it gives them as faithfully as the proto-sulphate of iron, it will be the developer *par excellence*, because it keeps very well in a corked bottle, when concentrated, and it is sufficient to dilute it with four or five parts of water to have it always ready for use.

By adding an imperceptible quantity of ordinary sulphate of iron to a proto-nitrate that works well, we succeed in making it act quicker; this is useless with the proto-acetate, which works quick enough. I have thought of employing these solutions in a warm state, but this deviation produced the worst results at every increase of temperature; for, these developers are of an excessively delicate nature.—*La Lumière*.

AN APOLOGY FOR ART-PHOTOGRAPHY.*

BY O. G. REJLANDER.

SOME time ago you did me the honour to elect me an honorary member of this Society. I felt it to be an honour, and take this opportunity of returning you my warmest thanks for the distinction.

I have diligently read the reports of the meetings of the South London Photographic Society, and find that there is no branch of photography with which you are not thoroughly conversant. What has pleased me most in your proceedings has been the earnest interest you have shown, and the encouragement you have given, in raising the science we practice to the dignity of a fine art. Such course, however, has been much misunderstood by friends and foes, and as I am an old sinner in that direction I have come forward to be the "horrid example," show my complicity, and present AN APOLOGY FOR ART-PHOTOGRAPHY.

In doing so allow me, in the first place, to explain how I first tumbled into photographic art, and how I have been "bobbing around" ever since, without being able to benefit myself in the way I have been preaching to others.

I had always a hope that I should be able to sit down and paint with the aid of those photographs that I had invented, and grieved I have often been to send out gems for others to paint from; but the fact is that my experiments have cost me so much, and my *clientèle* been so small, I have never been able to get the upper hand. Commercially, the cost has been to me sometimes more than what I earned; and it is impossible to have a painting in hand—a lone man—and run backwards and forwards from the camera to the drying pallet; so I must stick to the camera for my living, though in my own way.

In 1852 I was in Rome, and saw photographs of the *Apollo Belvidere*, the *Luocoon*, the *Torso*, Gibson's *Venus*, &c., &c., which I bought and studied; and I was delighted to have a fair chance of measuring the relative proportions of the antique on the flat and true copies of the originals. That was my first acquaintance with the fair results of photography. I merely recollected having seen some reddish landscape photographs the year before at Aekermann's, in Regent Street, but these made no impression on me. What I saw in the Exhibition of

* Read at a meeting of the South London Photographic Society, Feb. 12th, 1863.

1851 had proved as evanescent as looking at myself in a glass—"out of sight out of mind." They were all Daguerreotypes, and awakened in me at the moment nothing but curiosity. But in Rome I was fairly taken with the capabilities of the art, so I made up my mind to study photography as soon as I returned to England.

My view at this period, to the best of my recollection, did not extend farther than showing me the usefulness of photography in enabling me to take children's portraits, in aid of painting, and for studies for foregrounds in landscapes.

In 1853, having inquired in London for a good teacher, I was directed to Henneman. We agreed for so much for three or five lessons; but, as I was in a hurry to get back to the country, I took all the lessons during one afternoon!—three hours in the calotype and waxed-paper process, and half-an-hour sufficed for the collodion process!! He spoke, I wrote; but I was too clever. It would have saved me a year or more of trouble and expense had I attended carefully to the rudiments of the art for a month.

It is curious to notice how frequently trifles decide some men's actions. What really hurried me forward was my having seen the photograph of a gentleman, and the fold in his coat sleeve was just the very thing I required for a portrait I was then painting at home, and could not please myself in this particular point. My sitter had not time or inclination to sit for it; my lay figure was too thin (I soon sold that); but this was just "like life!" "Now," said I, "I shall get all I want." I could not exercise proper patience. I therefore took all the lessons at once, to turn out as a ready-made photographer the next day. Alas! for a very long period my attempts at photography resembled those of a young Miss at the piano, looking alternately at the music and the keys. If I had to speak at the time of operation, I very easily went wrong—often drawing up the shutter of the plate-holder with the collodionised plate outside.

I wish here also to add my acknowledgment that in my early photographic education my guide and comforter was Professor Hunt's Manual—that, even then—contained the germs of most of the processes since enlarged upon.

I cannot forbear mentioning that some of the earliest portraits that I took, and which I had sensitized with ammonia-nitrate, are as vigorous now as they were then, although they had but three changes of water—ten minutes or a quarter of an hour in each dish after hypo, as my instructor had told me—while others and later, according to the usual process, have proved as treacherous as a bad memory. At length Maxwell Lyte let his light in on my manipulations by the publication of the alkaline gold-toning process. At that time I was nearly giving up photography. I felt as if I were only writing in sand.

My first attempt at "double printing," as some call it, was exhibited in London in 1855. It was named in the catalogue *Group Printed from Three Negatives*. That plan I hit upon through sheer vexation, because I could not get a gentleman's figure in focus, though he was close behind a sofa on which two ladies were seated. Up to this time I considered postures on the principle of *bas-reliefs*—that is, with as few foreshortenings as possible; but now I felt freer.

I will now tell you how I first drifted into [making photographic pictures; and it seems to me that any one might excuse me—even Mr. Sutton—after hearing it. I had taken a group of two. They were expressive and composed well. The light was good, and the chemistry of it successful. A very good artist was staying in the neighbourhood, engaged on some commission. He called, saw this picture, was very much delighted with it, and so was I. Before he left my house he looked at the picture again, and said it was "marvellous;" but added:—"Now, if I had drawn that, I should have introduced another figure between them, or some light object to keep them together. You see there is where you photographers are at fault. Good morning!" I snapped my fingers after he left—but not at him—and exclaimed aloud, "I can do it!" Two days afterwards I called at my artist-friend's hotel as proud as anybody. He looked at my picture and at me, and took snuff twice. He said—"This is another picture." "No," said I, "it is the same, except with the addition you suggested." "Never!" he exclaimed; "and how is it possible? You should patent that!" * * * Well, our interview ended with another suggestion that if a basket or something else had been on the left side in the foreground it would have given greater depth to the picture, and adding that the light dress of the female on the shady side was not shady or dark enough. I agreed fully with my friend's criticism; and, after a week, I

sent to him, to London, the picture amended as at present. He wrote some time afterwards and thanked me, saying that it was very successful; but (he wrote), of course, now that that was known, any one who practised photography could do it.

* * * This was my first sip at the sweet and bitter cup in my photographic career.* A thought of the share he had in this first effort in composition-photography did not occur to my friend. I should very likely not have done it but for his "you can't!" Now why should this cause all the fuss and abuse for interfering with legitimate art? To me double printing seems most natural. Vignetting is allowed and admired. The manual part of photographic composition is but wholesale vignetting. It has proved most useful in portraiture when a family group was to be taken; for if one figure moved, he or she could be taken over again alone, and put in afterwards; or, what is still better, a sketch of the group may first be made, then take each figure separately—for then each would be more perfect—and print them in agreeably with the sketch.

But please to believe that I did not look upon photography as an ultimate art, or an art depending on itself, or complete in itself, except details; though I can guess of its extended applicability, or rather plasticity. In almost all the art-studies I have made, I have had one object in view—they were for the use of artists; and if I had not done them, how could artists, who are not acquainted with photography, know what could be done? They know now, and they avail themselves of it.

But as there is no mind in the photographic picture, so according to some it cannot contain any new idea, pose, light, or expression capable of representing impressions produced on the human mind, and "not being the work of man," it must be, indirectly, the work of the devil—and, since as "the work of man is indirectly the work of God," as Mr. Sutton has it, where are we to go to?

Still I think highly of photography. It is fair, open, and above-board. There is no sham about it—no pretensions to anything that is not discernible. And the world wouldn't be without it, in all its branches—including the one I most practise, art-studies and details from the life. Though to me this branch of the art is unprofitable, yet it gives me pleasure. I live in it, if not by it. As to those dreadful composition photographs, I have only executed one since the "abominable" "Two Ways of Life," and that one I meant as a set-off to the other, and called it the "Scripture Reader;" but that was neither good nor bad enough to attract any notice whatever. I have not exhibited for some years, so I think I might have been let alone.

I have been so ill-used and abused about the picture, the "Two Ways of Life," I should be glad to once more—not describe it, as I did to the Central Society—but explain that it was dedicated to English artists, which dedication was written under the one exhibited at the Manchester Exhibition;—not as a challenge, for that would have been ridiculous, but to show various studies from nature, which at that time were rather novel. And again, as the most difficult drawing is that from the living model, I presumed thereby to point out a handmaid to art—not alone in full light, but in shade—yet transparent. Each figure was meant as a specimen of variety of light and shade. I dislike a mere nude, if it (apart from study) conveys no idea. So I brought all the figures together as well as I could, and gave the resulting picture a name. This composition was also meant to show that there might be a little real sun-painting employed when needed, to harmonise or soften harsher light in photographs. These are indeed no after-thoughts.

I will not tire you with further description. Those that objected to the "Two Ways of Life" being exhibited had a perfect right to their opinion; but they have no right to ask the names or profession or religion of models, still less to use vile epithets in speaking of them, as Mr. Sutton has done in his paper read before the Photographic Society of Scotland. When children are inconveniently inquisitive, we tell them they were "found in a parsley bed;" and a similar answer might be given to those who cannot or will not comprehend the matter. There are many female models whose good name is as dear to them as to any other woman. But I prefer to believe that Mr. Sutton did not use those harsh expressions on mere supposition; but that he may have been misinformed, in his search for the truth, by those who wished to increase their attraction by saying

* It is not difficult to understand the vague notions of an artist the first time he sees such a thing accomplished—such a result in so short a time—when compared with his own laborious method.

that they had been models for Mr. So and So; for I have been told that that is not an uncommon practice. Of course I need not be ashamed to say I have heard it.

Mr. Sutton is a very hasty writer, and is often wrong in consequence; yet he is always frank enough to admit his error when convinced that he is wrong. This opinion is formed on my long reading of the "Notes," to which I have been a subscriber from its first publication, until I removed to London, when I missed it, or it has missed me, owing to my having forgotten to send my new address. I have always found the "Notes" full of promising information.

It is very hard—but I must confess it—that I positively dare not now make a composition photograph, even if I thought that it might be very perfect. I have brought with me a sketch over which I have thought for a very long time. Up to this moment it is a work of art. Is it not? The same way a painter goes if he means to paint a photographer must go if he wishes to make a composition-photograph. The two go together—part here, and meet again.

Fine art consists of many parts; and a photographic composition commenced in this manner must contain many parts in common with art; and even where they part company photographic art does not stand still, but proceeds and gathers other merits on another road—though a more humble one, yet full of difficulties, requiring much thought and skill up to the last moment, when they again converge, in the production of light, shade, and reflected lights which have been predetermined—in general keeping and aerial perspective.

There is no valid reason for saying that, because you have not seen a good photographic composition, there could not be one. I believe there can be produced—even after all that has been done—wonderful pictures by photography. And why are there no good art photographs? Because it requires art and long training to execute them, beside encouragement. I do not believe in haphazard excellence. Photography, in my opinion, is essentially excellent for details. You may take twenty good figures separately, but they cannot be taken at once. You cannot take even four good ones at once; but then you cannot draw or paint a picture at once.

I believe photography will make painters better artists and more careful draughtsmen. You may test their figures by photography. In Titian's "Venus and Adonis," Venus has her head turned in a manner that no female could turn it and at the same time show so much of her back. Her right leg also is too long. I have proved the correctness of this opinion by photography with variously-shaped female models. In "Peace and War," by Rubens, the back of the female with the basket is painted from a male, as proved by the same test.

The real good old painters—such as Raffaele, Leonardo da Vinci, Luini, Velasquez, Teniers, Titian—you often find reflected in photography in apparent finish and effect. I can exemplify presently what I mean by the photographs which are now before you.

There are many ways in which photography can prove useful to artists, although few of them are aware of it. Here is one:—After they have made their sketch, or uncoloured cartoon, they may have a photograph taken from it; and then on the prepared albumen paper they may play with colours as much as they like, until they arrive at what they wish for their painting; for a wet brush removes any colour objected to, just as if it had never been there, yet the outline underneath remains the same.

One of the reasons why painters are troubled in using a photograph to print from, is that almost in every case (I am now speaking of portraits or figure pictures) the light on the photograph is different to that on the sitter at the artist's studio. Here is a source of confusion and vexation. I have often felt it, and wished that I had not looked at the photograph; yet it saved the time of the sitter. But if a photographic study is taken in a light similar to that at artists' studios generally, and that be enlarged, if the artist gets the same model or sitter into his own studio, the work is only pleasure.

I think picture-dealers are, or have been, from interested motives, the greatest opponents to photography, and they have great influence. As to art-critics, they vary so much in their opinion from one year to another, and differ so much between themselves, I am induced to conclude that they write generally from the information they have received from persons they trust to; for I believe if they possessed even the data that we have, they would be more Christian like—rather help with their criti-

cism than damn with their sneers. Though individually I must not complain much. I have had praise, and I was silent. Lately the tables have been turned, and from a "successful delineator," &c.,—happy in catching transient expressions—I had come down to be a "clever operator," when recently I was reduced to the position of a "manipulator" in a notice—and such a notice!—in the *Athenæum*, of an allegorically-treated photograph of "Garibaldi Wounded, Supported by Hope, Pointing to Rome." My intention in this photograph was to show that my opinion of the hero was that he never would give up the idea of possessing Rome. But in the notice in the *Athenæum** above alluded to, I was rudely taken to task. It was intimated that I had paid my model 1s. 6d. per hour, when I myself was the model, and never realised 6d. per hour! After my many days' trials, and heavy printing expenses, my publisher ceased to order immediately upon that veto being placed upon the picture. I hoped to have secured an adequate return from its publication: I never had a catchpenny yet. But what angered me most was that the critic called the photograph indecent! I cannot guess in what.

A funny thing it is that some people actually prefer the chalkings of a boy on the walls and shutter to the finest photographic pictures! Just think how superior are the mackerel and ship at sea we find drawn on the pavement in coloured chalks! I am ambitious, too!

I have here a picture,† in which I have attempted to draw something, like a good boy, and beg the Chairman's acceptance of it. I only wish there had been another sunny day, to have enabled me to have made it more perfect. It is a real sun-painting, or rather it has been painted by me with pencils of light about ninety-three millions of miles long! and the points varying considerably. I exposed it so much to diffused daylight for want of sun, that I have been obliged to take up some lights still that have been done chemically by the cyanide of potassium. When I painted it I almost imagined I heard its notes whistling.—Now, USE PHOTOGRAPHY; DON'T ABUSE IT.

THOMAS SUTTON, B.A., ON ART-PHOTOGRAPHY.

BY ALFRED H. WALL. ‡

SAITH Atticus—"Let every man enjoy his own spouse;" and I have no reason on earth for denying every man his right so to do, providing only that such spouse be quite legitimately his own.

But the man who enjoys one spouse while he has another living I conceive that I have a perfect right to denounce as guilty of no less a crime than bigamy; and that, gentlemen, as your worthy Treasurer will inform you, is against the law.

Before this bar of public opinion, and in the interests of one of two spouses thus enjoyed, I therefore charge Thomas Sutton, B.A., editor of the *Photographic Notes* with flat, downright, open and avowed bigamy. For that, whereas, up to the year 1860, he had openly announced himself as wedded to *Art-Photography*, he in that identical and aforesaid year did publicly espouse *Mechanical Photography*. And in support of this charge I beg leave to introduce the following witnesses:

My first witness is a valuable little work on "The Positive Collodion Process," written by Mr. Sutton in 1857, which says—*"Photographic portraiture is not a mechanical art. It involves the application of certain principles of art."*

My next witness is the *Photographic Notes*, dato 1860, which very wisely remarks:—"Although photography is certainly a mechanical means of representing Nature, yet, when we compare a really fine photograph with an ordinary mechanical view, we are compelled to admit that it exhibits mind, and appreciation of the beautiful, and skill in selection and treatment of the subject on the part of the photographer, to a degree which constitutes him an artist in a high sense of the word."

My third witness is a number of the *Photographic Notes* published in 1862, which remarks of the productions of T. R. Williams, that "sentiment and grace" are infused into them by the artist, and that to such an "extraordinary extent that they are quite undistinguishable from the fine works of art."

Here, then, we see Mr. Sutton holding within his fondly-encircling arms the first love of his fickle heart,—Art-

* "I wish I was in Dixie! I do! I do!"

† A donkey's head, drawn by light alone, guided by me.

‡ Read at a meeting of the South London Photographic Society, on Thursday Evening, Feb. 12th.

photography—recognized, as we see, in 1857, and not disowned entirely in 1862.

To prove the existence of the second "spouse," and that she was wedded before any legitimate separation had divided Mr. Sutton from his first spouse, is the business of my next following witnesses.

Witness No. 4 is a number of the *Photographic Notes* for September, 1861, and says—"Photography has its peculiar value as a handmaid of the fine arts, but it is not one of them." This witness, moreover, gives as a reason for such a conclusion, that "the essence of art is to suppress coarse particulars," which "the camera has no power of rejecting;" and that if the photographer removes these "coarse particulars" so that the camera can have no power of recording them, although the photographer is then admitted to be an artist, still photography is not art.

In dismissing this witness, I would, if the poor thing were not already sufficiently confused, commence a cross-examination to discover how the man could be an artist by virtue of works not the production of an art.*

Witness No. 5 is a paper by Mr. Sutton, read before the *Photographic Society of Scotland* on the 13th of January, 1863, which completes my case by asserting that "the first chalk drawings of a school-boy on a wall are" (in the opinion of Mr. Thomas Sutton, B.A., &c.) "more admirable, from the human interest which they possess, than the finest view of inanimate natural objects upon the ground-glass of a camera-obscura.

As I am not in possession of more than a few numbers of the *Photographic Notes*, and have not time to look carefully through even the few I have, no more witnesses will be called, although I have in remembrance the words of many others capable of giving even more conclusive evidence than that I have advanced. Still, I believe the case, even as it here stands, will be found tolerably clear and conclusive, and that the verdict will be in accordance with the evidence and with truth.

To quit joking, however, I wish to tender a few remarks concerning a paper written by Mr. Sutton, "On some of the Uses and Abuses of Photography," or rather upon that portion of it which refers to the so-styled "abuses."

Mr. Sutton commences this portion of his paper by saying that everything in the way of composition photography which he has seen, by Messrs. Robinson and Rejlander, "has been a failure, and has afforded increasing evidence of what every true artist knew before to be impossible and opposed to correct principles. What you want in a work of art" (says Mr. Sutton) "is not an exact and truthful resemblance of a group of natural objects, however cleverly arranged and lighted, but a reproduction of such objects, or a new combination of such objects, according to impressions that they have produced on the human mind."† And then follows that truly remarkable paragraph to which I have already referred, concerning the school-boy's first chalk drawings on one of my more illustrious namesakes.

The question thus stated by Mr. Sutton simply resolves itself into that old, old question on which artists and artistic critics have themselves been divided for very many years past. Long before photography was dreamt of in our philosophy, the degree and character of truth which ought to be embodied in the highest aspirations of art were a source of continual discussion and contention in all the various schools. But in none of these schools however strong party influence or feeling might run, was there ever found an advocate for the ideal in art so extravagant as to assert of truthful art that it was not art at all. This has been reserved for Mr. Sutton.

But the question of artistic *versus* mechanical photography will never be decided on these grounds of the real and the ideal. Upon the evidence afforded by simple truthfulness of imitation, photography can neither be denied nor awarded a place among the fine arts. Every art which aspires to the distinction implied by the term "Fine Art," must base its claims upon the amount and degree of intellectual power of which it can be made the vehicle. If we find that photography can convey as much of the artistic intellect into the minds of spectators as any other art called "fine" has the power of doing, then, and then only, is photography a fine art. By this test I ask that photography shall be judged; and if such works as those of Rejlander and Robinson be allowed to plead in the minds of competent

and unprejudiced witnesses, I have little fear of the decision which must be arrived at.

On this subject of true and ideal art I know no one who has said more in fewer words than that eminent and high authority, Mr. Ruskin, has done in the following:—"Every alteration of the features of nature has its origin either in powerless indolence or blind audacity—in the folly which forgets, or the insolence which desecrates, works which it is the pride of angels to know and their privilege to love."

In contrast with this noble sentiment of a humble and reverential love for the works of the Divinity, emanating from the soul of a true artist, let us place the following, uttered, in the paper I have mentioned, by Mr. Sutton:—"God created these objects and He also created man; and man's works are therefore indirectly His works. But man is the noblest creation of the Deity; and if you follow up the train of thought you will see that pictures which are the result of human imagination, observation, and powers of imagination* are more noble and belong to a different class of things altogether from the images in a camera-obscura.

I must confess that any clue to the train of thought Mr. Sutton here refers to is, to me, perfectly invisible; for I cannot of course conceive that Mr. Sutton is so blindly audacious, so forgetfully foolish, or so sacrilegiously insolent (to give Mr. Ruskin's words their legitimate application) as to claim greater superiority for the works of man than for those of God, as represented in all their glorious perfection on the ground-glass of the camera-obscura.

Putting aside the abstract question of reality and ideality, then, as being no concern of ours (for I cannot conceive that even Mr. Sutton would deny the claim of the minutely and quite photographically truthful paintings of the Dutch school to be considered works of art), let us turn to Mr. Sutton's attack upon photographic studies from the nude, which runs as follows:—

"When the Council of this Society [the Photographic Society of Scotland] some years ago, banished from the walls of its exhibition a photograph entitled 'The two Ways of Life,' in which degraded females were exhibited in a state of nudity, with all the uncompromising truthfulness of photography, they did quite right, for there was neither art nor decency in such a photograph; and if I expressed a different opinion at the time I was wrong. There is no impropriety in exhibiting such works of art as Etty's 'Bathers Surprised by a Swan,' or the 'Judgment of Paris;' but there is impropriety in allowing the public to see photographs of nude prostitutes, in flesh-and-blood truthfulness and minuteness of detail."

The great sting of this attack is perhaps intended to reside in such terms as "degraded females" and "nude prostitutes;" but Mr. Sutton has no more right to scatter his foul words among the models chosen by Mr. Rejlander for his beautiful photographs, than he would have to apply the same coarse expressions to the models Mr. Etty painted from in producing the identical pictures he mentions. Mrs. Grundy and Mr. Sutton notwithstanding, it is by no means impossible that the very models thus publicly stigmatized as "degraded prostitutes," because they sat as studies to Mr. Rejlander, may be really respectable wives and mothers. Of course, I use the word "respectable" in its anti-Grundy sense.†

If, however, Mr. Sutton objects to the representation of nude models, simply because he imagines that they should be idealized or conventionalized, before their images are fit to be presented to what he must evidently regard as a lascivious-minded, British public, then I have another answer for him.

Canova, the great sculptor, in a letter to the Earl of Elgin, concerning those celebrated works of Greek art, the Elgin marbles, says:—"I admire in them the truth of nature, united to the finest forms. Everything here breathes life. The naked is perfect flesh, and most beautiful of its kind. I think myself happy in having been able to see with my own eyes these distinguished works, and I should feel perfectly satisfied if I had come to London only to view them." Haydon, the historical painter, says of these same glorious and unequalled productions, that, "having dissected man and animal for two years," he saw in this sculpture "every tendon, bone, and muscle distinguished from each other in substance and shape, and always indicated where nature indicated them;" and adds that, therefore, "it

* "It—the camera—treats everything alike, and if the man interferes and alters the arrangement of things that nothing objectionable shall be presented to the camera. His art consists in making that arrangement, and not in afterwards taking a photograph of it."—*Notes* for September 1st, 1861.

† These italics are Mr. Sutton's.

* The italics are Mr. Sutton's.

† In reading this, it must be remembered that the writer is an artist who has himself studied from the nude, and is, therefore, familiar with the general characteristics of artists' models.

was nothing but natural that he should at once recognise their superiority to all other sculpture, because in no other sculpture was this system of nature so distinctly clear." Enthusiastically dwelling upon their truth and beauty, poor Haydon added, that he "would joyfully have died in their defence." Hazlitt, the popular art-critic, says of these same miracles of art:—"The communication of art with nature is here everywhere immediate, entire, palpable. The artist gives himself no fastidious airs of superiority over what he sees. He has not arrived at that stage of his progress, described at much length in Sir Joshua Reynolds's discourses, in which, having served out his apprenticeship to Nature, he can set up for himself in opposition to her. . . . We can compare these marbles to nothing but the human form purified; they have every appearance of absolute *facsimiles*, or casts taken from nature. . . . Let any one, for instance, look at the leg of the *Ilissus* or *River God*, which is bent under him: let him observe the swell and undulation of the calf, the inner texture of the muscles, the distinction and union of all the parts, and the effect of action everywhere impressed on the external form, as if the very marble were a flexible substance, and contained the various springs of life and motion within itself, and he will own that art and nature are here the same thing." Referring to some advocates of the ideal in art who urged that in the *Elgin Marbles* the real and the ideal are only combined with very extraordinary skill, Hazlitt replies:—"If by *ideal forms* they mean fine natural forms, we have nothing to object; but if they mean that the sculptors of the *Theseus* and *Ilissus* got the forms out of their own heads, and then tacked the truth of nature to them, we can only say, 'Let them look again! let them look again!' We consider the *Elgin Marbles* as a demonstration of the impossibility of separating art from nature, without a proportionate loss at every remove. . . . The truth of nature is incompatible with ideal form, if the latter is meant to exclude actually existing form." This same able art-writer then goes on to say:—"That truth of nature and ideal or fine form are not always, or generally united, we know; but how they can ever be united in art, without being first united in nature, is to us a mystery, and one that we as little believe as understand."

To make the illustration thus supplied by a writer of position (speaking, it must be remembered, before photography existed) the more remarkable, I shall give one more quotation, in which Hazlitt writes:—"Suppose, for illustration's sake, that these marbles were originally done as casts from actual nature; and then let us inquire, whether they would not have possessed all the same qualities that they now display, granting only that the forms were in the first instance selected with the eye of taste, and disposed with knowledge of the art and of the subject."

This inquiry is most conclusively answered in the affirmative. "Incontestably there would have been, besides the same grandeur of form, all the *minutiae* and individual details in the cast that subsist in nature, and that find no place in *ideal art*. . . . The veins, the wrinkles in the skin, the indications of the muscles under the skin, the finger joints, the nails, even the smallest part cognisable to the naked eye, would be given with the same prominence and the same subordination. . . . Therefore, so far these things—viz., nature, a cast from it, and the *Elgin Marbles*—are the same; and all three are opposed to the fashionable and fastidious theory of the ideal."*

What becomes of Mr. Sutton's disgust at "flesh-and-blood truthfulness, and minuteness of detail," in the face of such proofs as are supplied by the *Elgin Marbles*, and such opinions as are here, by voices of the greatest authority, so emphatically expressed? No higher or more widely-recognized authority, and none more conclusively eloquent in favour of absolute truth in studies from the nude, can possibly be advanced than will be found in these marbles, many of which were undoubtedly, if our best records of ancient art may be relied upon, faithfully copied from what Mr. Sutton chooses to call "prostitutes," or "degraded women." Phryno, whose beauty preserved here life, courtesan though she was, has won world renown as the "Venus of Cnidos," and her golden image took its place among those "consecrated by public piety."

In conclusion, I will quote Cowley, the good old poet, to show how far from new this controversy of the real and the ideal is:—

* The author greatly regrets that he cannot here give all the powerful arguments and demonstrations by which Hazlitt urges that, even if mechanically produced, these works are the very highest and most perfect art.

"Who to the life an exact piece would make,
Must not from others' work a copy take.
No, not from Rubens or Vandyke,
Much less content himself to make it lie
The ideas and the images which lie
In his own fancy or his memory.
No: he before his sight must place
The natural and living face;
The real object must command
Each judgment of his eye and motion of his hand."

THE APPLICATION OF PHOTOGRAPHY TO THE MAGIC LANTERN EDUCATIONALLY CONSIDERED.

BY SAMUEL HIGHLEY, F.G.S., &c.*

LECTURER'S DEMONSTRATING LANTERN.—The best form of lantern for lecturers or institutions is one made in mahogany (the older the stuff, of which it is constructed, the better), twelve inches square, and twenty inches high, fitted with two jets and two nozzles, the lower one being used for lantern views, the upper one is fixed on a hinged panel, so that if a dissolving view arrangement is desired, the two discs on the screen may be made to coincide by depressing the upper nozzle by the action of a spring and screw adjustment. The upper nozzle may be replaced by a microscope arrangement, or a polariscope, and to the flange of the lower nozzle various pieces, such as knife-edge slit plates may be fitted for Spectrum Analysis, or other optical experiments. To economise space and cost of production, in place of the ordinary chimney, I use a flat dome of iron, fitted with side plates, so that by raising the dome or lid from behind, ventilation is secured, while the egress of light is prevented by the angular side-screens. Instead of the ordinary dissolving view fan, which I dispense with *in toto*, I make one view die away while the other brightens, by means of alternating gas-taps (that admit the oxygen supply), worked by a lever arm, all of which improvements are shown in section, in Fig. 10.

Fig. 10.

The optical parts consist of the condensers, which are formed of a meniscus and a crossed lens, and the front lenses, which should be achromatic combinations, adjustable by a tube sliding in a cloth-lined jacket, or by a rack and pinion motion.

The lenses should separate, so that while in combination they may give an obtused-angled dispersion to the rays of light, and then be used near a screen of moderate diameter, and when the back lens is removed, an acute-angled dispersion, so as to be suited for a large screen placed at a considerable distance from the lantern. By the latter arrangement, at an equal distance from the screen, a smaller, but consequently a brighter, picture is secured, as the same amount of light is not diffused over so

* Continued from p. 82.

large a surface as when the two combinations are used together.

If this lantern is to be employed by a travelling lecturer, I would suggest the adoption of an arrangement I exhibited at the International Exhibition, and which stands upon the floor; it consists of a zinc gasometer, enclosed in a wooden casing; within the body of the bell, the lantern is packed, while a case containing the jets, nozzles, &c., fits within the body of the lantern, as shewn in Fig. 11.

Fig. 11.

When the parts are unpacked four rods screw into the corner of the outer case of the gasometer, on to the top of these the folding lid clamps, and then forms a table for the lantern and slides as shown in Fig. 12, while the bell of the gasometer is capable of holding sufficient oxygen for an hour's lecture (or longer).

Fig. 12.

The lantern case of fittings, and gasometer, when packed, occupy a space of 14 by 15 inches square by 24 inches in height. The four iron rods strap together as a separate package.

If, however, the lantern is to be in constant use at an Institution for demonstrations, pictorial or optical, then the lecture-room stand I have devised is more convenient. By rackwork

and turn-table adjustments, the lantern placed on its stage can be centred with any piece of optical apparatus; or, when required for views, it can, by a telescopic slide in the supporting bars, be carried up to the centre of a screen five or seven feet from the ground. By turning the folding flap back at any desired angle, and placing the lantern upon it, the rays of light might be projected upwards or downwards, as may be desired, according to the way the nozzle is placed in reference to the incline of the flap-table. I do not mount my photographs in separate frames, but, to economise space, pack them in grooved boxes like those used by photographers, and employ a pair of "view-holders." These open like a book, the slide is dropped into a square cell, and on the flap being shut and clamped by a turn-buckle of peculiar construction, the view is kept firm by four springs pressing on the corners, as shewn in Fig. 13.

On a view-holder being taken from the lantern it is replaced by its fellow holder, and during the description of the subject on the screen, it is opened, the previous slide removed from its cell, dropped into its groove in the stock box, and replaced by the next subject, and the two view-holders are thus kept alternating.

With regard to screens, they may be transparent or opaque, the latter being distempred in "flatted" white by any method that prevents the surface from cracking when rolled up. Opaque screens can be made as large as ten feet in diameter,

Fig. 13.

and up to this size may be conveniently mounted, like library maps, in cornice rollers. Beyond this size, they should be constructed of calico sheeting, as they then fold into a small space for the purposes of carriage, and when mounted may be strained by strong poles jointed together like a fishing rod. The smaller screens may be supported, and strained on a portable folding stand I have designed, a model of which is placed on the table.

The advantages I claim, then, for magic lantern views, over those in general use, when educational value is aimed at, are delineations truthful to nature, and abounding in detail, cheapness, compactness, as compared with paper diagrams, and their utility in museums, when not in use for their legitimate purpose.

(To be continued.)

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The usual monthly meeting was held in the City of London College, on the evening of Thursday, February 12th, Mr. SEBASTIAN DAVIS in the chair.

The minutes of a previous meeting having been read and confirmed, the following gentlemen were elected members of the Society:—Messrs. C. Smartt, T. R. Williams, J. H. Dallmeyer, T. R. Mills, Henry Squire, and C. E. Elliott.

A parcel of two-ounce bottles of bromo-iodized collodion, by Messrs. HORNE and THORNTHWAITHE, was placed upon the table as a present from that firm to the Society, each member being requested to accept a bottle. It was explained by Mr. Martin that the collodion was believed to be of unusually fine quality, and he read a note received from Messrs. Ross and Thompson, of Edinburgh, ordering six pints as early as possible, and remarking that it was the very best collodion they had used. We may here, with propriety, add that since the meeting we have tried the collodion and found it fully justify the encomiums it had received. It is very rapid, clear, and brilliant; full-bodied, giving a rich creamy film, and yielding fine half tone, clean shadows, and dense lights, the negative being in some cases

sufficiently vigorous with simple iron development without intensifying.

Mr. SQUIRE exhibited a variety of photographs illustrating the capabilities of Shepherd and Co.'s lenses, amongst which were some fine instantaneous stereographs of scenes in the neighbourhood of Plymouth. He also exhibited a novel printing frame, in which facilities existed for printing half-a-dozen card portraits on separate negatives, the arrangement permitting not only the easy examination of each, but of removing any print and negative without disturbing the others. He also exhibited a rolling press for card pictures, after the design of Coleman Sellers.

It was explained by the Chairman that the exquisite card picture consisting of a view of Edinburgh from Calton Hill, with fine natural clouds, which had been so much admired at the last meeting, was by Mr. Archibald Burns, and that some of them were ready for distribution amongst the members, in accordance with the resolution of the last meeting. He hoped that all would be ready by the next meeting. In the mean time, those members who chose to send to Mr. Wharton Simpson a stamped and addressed envelope might receive copies without delay.

Mr. REJLANDER's paper, "An Apology for Art Photography" (see p. 88), was then read by Mr. Wharton Simpson, Mr. Rejlander himself suffering from some indisposition. At the conclusion of the paper, Mr. Rejlander handed round for inspection a couple of pictures, consisting of donkeys' heads, drawn by light on sensitive paper without the aid of negative or camera; the pencil of the sunbeam simply being wielded by Mr. Rejlander's hand. He also exhibited a sketch showing the plan of his studio, in which a much smaller amount of glass than usual is employed, the especial object being to produce studies for painters; the mode of lighting is intended to produce similar results to those obtained in the studio of the painter. A group designed for a composition picture, as referred to in the paper, was examined with much interest.

Mr. WALL, in continuation of the discussion, read a paper entitled "Thomas Sutton, B.A., on Art Photography" (see p. 89).

Mr. REJLANDER then laid before the members a choice selection of photographic studies from his portfolio. Some of these were selected with a view to illustrate the plasticity of photography in producing effects, and faithfully imitating in life, studies in the style or manner of various great masters, amongst whom were Raphael, Velasquez, Titian, Teniers, and others. In some the test of photography had been applied to the drawings of Raphael, in which the figures were in peculiar action, or unusually lighted; and, as Mr. Rejlander observed, it was as pleasant to observe that the test of photography proved the truth of drawing in the muscular action and anatomy of Raphael's figures, as it was to know that effects so similar to those of the great master could be produced by photography. Others illustrated how, by the posing and action only, a sentiment could be expressed or a story told. This was shown by a charming pair of studies entitled "Cupid in Trouble and Cupid in Despair," the action in the latter, in which the baby model leans forward grasping his leg, being wonderfully expressive.

Another picture illustrated a similar idea, showing how a story could be told, and expression thrown into a picture produced by the aid of lay figures only. It was an allegorical picture, the title of which we forget, but which might have been called a "Dream of Life." A male figure is laid sleeping, and his dream is indicated by the aid of a mysterious-looking article, in shape like a hollow truncated cone, consisting of a series of rings, or hoops, known, we believe, by the initiated, as a "crinoline." On these hoops, as on the bars of a ladder, the small lay figures were climbing, the different action and positions aptly displaying character and intention. Some were resting happy and content on the lower round of the ladder, whilst others toiled eagerly forward far above them; some had dashed forward with such precipitancy that, having nearly attained the summit, they then missed their footing and were tumbling headlong, whilst others—very few—having reached the topmost round, look calmly or proudly down on the toilers below.

A charming study of a child, smiling and interested, called by Mr. Rejlander, "Do it again," gave occasion for an anecdote of the mode in which the expression was obtained. The ordinary bribes of childhood had been insufficient to interest the little urchin, and a female attendant had, therefore, attempted the extraordinary feat of eating a nail, which was in the wall opposite to the child, who was mightily tickled, and exclaimed,

"Do it again," and whilst waiting, watching with amused interest for the feat to be done again, the portrait was secured.

Many other studies of expression were exhibited, with anecdotes of the mode in which they were secured. Studies of muscular action, of graceful action, of the nude, of drapery, &c., were also exhibited and explained during a desultory conversational discussion, in the course of which a gentleman present remarked, in confirmation of some remarks on the aid to the artist furnished by photography, that Burford's "Panorama of Rome" was painted by Mr. Selous from photographs of that city.

After a few remarks by the Chairman, a vote of thanks to Mr. Rejlander was moved by Mr. Simpson and seconded by Mr. Wall, who wished Mr. Rejlander's detractors had been present, as he thought the studies they had examined, and the comments and explanations they had heard, would have been sufficient to convince the most stubborn of the art claims of photography. The vote of thanks having been passed by acclamation,

Mr. REJLANDER, in acknowledging the vote, said, that in his endeavours to make photography an aid to the painter, he had almost been as modest as the most fastidious person could wish. Where he had in the service of art delineated by photography the nude figure, he had scrupulously avoided the violation of modesty, both in act and thought. He disliked immodesty, and in his pictures had always avoided it; and he was sure if those who had spoken of the indelicacy of his pictures knew the injustice they had done him, they would be sorry for it. However, when his pictures were condemned, he did not care about fighting, and instead of producing other composition pictures for which he might have to fight, he confined himself to studies for artists, which were often required most by those artists who most decried photographic aid. He had many conceptions, and should have liked to have produced many pictures but for this repression. In reference to the art claims of photography, it was undoubtedly a mechanical and chemical art, but it was capable of being applied as a fine art, and he hoped for the time when there would be a class for photography in the Royal Academy, under the guidance of approved artists. By this means, artists and photographers would get better to understand each other, and the capabilities and limits of their respective methods. Once more he thanked them, and if health permitted he hoped again perhaps to do something in composition photography. But he would bide his time.

Some prints were presented to the Society by Mr. Sidney Smith, and Mr. Price's paper "On the Theoretical Principles of Positive Printing" was deferred until the next meeting. The proceedings then terminated.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 11th Feb. 1863.

A new method of microphotography is proposed by M. H. Vogel, which is so simple, that any one, however little acquainted with operations of this nature, may easily avail himself of it. To a microscope, placed horizontally, a small photographic camera is adapted, fitted with a single achromatic landscape lens, of about 4" focal distance, and arranged in such manner that the optical axes of the two instruments coincide, and that the objective of the camera almost touches the eye-piece of the microscope. M. Vogel has also attempted to photograph telescopic images, but the undertaking was much more difficult, and the results hitherto obtained are not satisfactory.

MM. Bunsen and H. Roscoe have published, in *Poggendorff's Annals*, a very important article on the chemical action of light applied to the phenomena of the organic and mineral kingdoms. The learned authors propose to themselves to examine the modifications and the chemical effects which the surface of the earth is susceptible of receiving, either from the direct rays of the sun or from diffused light. These researches, extremely delicate, require new means of experimenting, into the details of which it is not possible to enter in this place. It must suffice to notice,

among the results obtained, that the chemical action of light, *photochemistry*, varies according to the geological constitution and the agricultural condition of the soil, the annual and diurnal obliquity of the rays, the hours of the day, the latitude and the seasons. The *maxima* of effects are remarked at the period of the solstices. In order to classify the phenomena, the points of equality might be united by lines, as is done with the distribution of heat on the terrestrial surface. We should thus obtain a set of *isophotochemical lines*, diurnal, monthly, and annual, and of unquestionable utility for the progress of general physics and meteorology, which are still in their infancy. But to realise this magnificent and difficult programme requires the union and co-operation of all the observers living in every quarter of the globe. A consummation which, unfortunately, is very unlikely to be attained.

M. A. d'Abbadie has presented a report to the Geographical Society, on *The Photographic Plane-Table*, invented by M. Auguste Chevallier,* in which he pays a warm tribute of admiration to the efforts of the persevering inventor in perfecting his apparatus. Geographic photography is placed between two extremes, one of which is the microscope, the other the telescope—the infinitely small and the infinitely great. It aims at employing the flat pictures, upon which are fixed the panoramic landscapes and varied plans, which the traveller perceives unfolded to his view in all their new and changeful details. But how shall we deduce the precise data of latitude, longitude, and altitude, that hidden but substantial framework which sustains the varied structure of a map? This problem has been ingeniously solved by M. Chevallier, who, disdaining the more enticing phases of the photographic art, has put aside the picturesque, and in his landscapes disregards only the relations essential to geography; or the forms and positions relative to the signals. To this end he has converted the photographic negative into a plane-table, and by a mechanical, and we may also add, automatic process, retained all the advantages of this elementary instrument, but which is, in the last analysis, the capital instrument of topography.

In using the ordinary plane-table we must carefully trace the lines which note the direction of each interesting signal, such as the angles of houses or fields, mouths of rivers, summits of mountains, &c.; we must afterwards write the name of each object projected, or, if ignorant of it, as is frequently the case in travelling, it is indispensable that an exact sketch of each signal noted be made, in order to recognise it at the new station to which the traveller repairs to set up again his plane-table. We may have already anticipated that photography employed in such a case will cause the sketching to be dispensed with, and provide a guarantee against the errors which may, in the sketches, seriously affect the accuracy of the essential details. Moreover these sketches demand much time; and experience has often proved to us that after having fixed upon a distant signal, atmospheric changes will veil it from the sight before there has been sufficient time to sketch its form. And this is not all: the ordinary plane-table does not admit of the projection of many objects very near together without introducing confusion into the work. Besides, it gives only the relative azimuths. It has therefore been found desirable to add to it a lens and a circle, or at least a graduated arc, to obtain the angle of height, or apozenith, an element indispensable for knowing the altitude of the signal. But then the instrument, although complete, becomes very complicated, like that invented by M. Porro, and most practical geographers prefer to replace the plane-table by a more precise instrument, which gives both the vertical and horizontal angles at the same time. The elements thus obtained, first transcribed in a register, must be repeated upon another sheet of paper by means of a transfer. And, after all, this method of observation does

not dispense with the minutious care of sketching each signal. And it is difficult for the energy of the topographic traveller to overcome all these obstacles. By the aid of photography he can accomplish in a quarter of an hour a more satisfactory result than in six hours without it.

It is easy enough to obtain a panorama of the horizon by means of photography, but it was a difficult task to give to the photographic plate all the advantages of an ordinary plane-table. M. Chevallier has solved this difficult and important problem. Other operators had shown, as he has done, that an objective, furnished with a rotary movement, can reproduce a panorama, without confounding the images in it by superposition; but what appears to specially constitute his discovery, is, that of being able to operate usefully upon a plane surface, by fixing his glass plate, coated with a sensitive film, upon a moving vertical wheel articulated at right angles, with a fixed horizontal wheel, the teeth of which force the vertical wheel to terminate a complete revolution upon itself at the precise moment when its horizontal axis has finished its tour of the horizon. The principle of this invention consists in the transformation of the horizontal movement of the camera into an equal but vertical movement of the glass plate, which registers the picture in a continuous manner. Beyond the well-known manipulation of photography, the employment of this instrument requires no other preliminary than the regulation of the level which the positive requires.

THE DISCUSSION ON ART PHOTOGRAPHY.

SIR,—I quite intended to have been present at the last meeting of the South London Society to take part in the discussion on the papers by Messrs. Wall and Rejlander, but the weather was so provokingly brilliant here last week that I was compelled to remain at home to take advantage of it. However, the papers read by those gentlemen so completely upset all that Mr. Sutton advanced against art-photography in his paper read before the Photographic Society of Scotland, that it would have been scarcely necessary for me to have said one word on the subject. Having been coupled by Mr. Sutton with Mr. Rejlander, as an offender against photographic propriety in the pictures I have produced, I have to thank the latter gentleman, and also Mr. Wall, for the very valuable and convincing arguments they employed in our defence, although I think the matter was not worth the trouble they took about it, for I am sure that if Mr. Sutton were left to himself for a little time, he would, with his usual heedlessness of consistency, turn round in favour of all he now opposes. The efforts of those who endeavoured to raise the character of our art having the approbation of every other journal devoted to photography, it cannot be of the slightest importance to them what are the present opinions of an editor who capriciously praises and condemns by turns.

HENRY P. ROBINSON.

Leamington, Feb. 16, 1863.

NO OUTLINE IN ART.—Mr. Ruskin, in speaking of his mode of teaching drawing at the Working Men's College, says, "There are no *outlines* in nature, and no pupil in my class is ever allowed to draw an outline"—arguing, it would appear, that as there is "no outline in nature," there should be no outline in art. Nature, he says, relieves one mass or one tint against another, but there is no outline. In theory, this is to a great extent true; but yet it is very convenient to the artist, in making a composition, to define by an *outline* how far and in what form a mass or a tint extends itself; and the effects produced by these artistic lines of demarcation are so agreeable to the eye in themselves, if done in a true artistic spirit, that many pleasing decorations may be made with outline alone. The outline sketches of some artists are indeed more sought for by the true connoisseur than the finished work in which they have been blended into the masses. Nevertheless, Mr. Ruskin's acutely perceived and ingeniously defended crotchets, though often untenable, are always full of suggestive hints of the highest artistic value.

* Vide PHOTOGRAPHIC NEWS, vol. vi. pp. 63, 77.

Talk in the Studio.

THE REV. T. F. HARDWICH.—Many of our readers will learn with pleasure of the publication of a portrait of Mr. Hardwich, who, although retired from the photographic world, is still kindly remembered by photographers. Mr. St. George has recently issued a card picture, which is a characteristic portrait and a brilliant photograph. We have pleasure in commending it to our readers, and we may also call attention to it as a specimen of fine printing.

ROBBERY OF LENSES AT THE CRYSTAL PALACE.—George Restall surrendered at the Surrey Sessions to take his trial upon an indictment charging him with stealing eighteen lenses, the property of his employers, Messrs. Negretti and Zambra, opticians, at the Crystal Palace. Mr. Robinson, with Mr. Oppenheim, for the prosecution; and Mr. Sleight, specially retained, with Mr. Thompson, conducted the defence. The evidence for the prosecution having closed, Mr. Sleight addressed the jury for the defence; when the Chairman summed up, and the jury, after an absence of nearly an hour, returned a verdict of guilty against the prisoner, with a strong recommendation to mercy on account of his previous good character. Sentence was postponed.

MOIST SENSITIVE PHOTOGRAPHIC PLATES.—A correspondent of the *Scientific American* says:—It has long been an object with photographers to keep prepared sensitive plates moist longer than ordinary, as it is well known that in a dry atmosphere, in doors or out, a sensitive plate will crystallize in a few minutes and be rendered unfit for use. My remedy is this:—Take newly-made plate frames and varnish them with gum shellac dissolved in alcohol, until the wood is thoroughly saturated; after being dried, immerse them in water for an hour, take them out, drain and wrap them in a wet towel, and place them in a box made of wood or leather, with a close lid. The towel should be wet daily, and the frames kept in the box. By these means, with a nitrate bath of thirty to thirty-five grains, I have no difficulty in keeping the plates two or three hours or more. I have had many inquiries about my process upon the supposition that there was some secret in the preparation of the plate; but it consists in preventing the evaporation of the moisture, and that is effectually done by the above method.

PHOTOGRAPHY AT THE SEAT OF WAR.—"Decidedly" says the *Corinth Tribune*, "one of the institutions of our army is the travelling portrait gallery. A camp is hardly pitched before one of the omnipresent artists in collodion and amber-varnish drives up his two-horse wagon, pitches his canvas gallery, and unpacks his chemicals. Our army here (Fredericksburg) is now so large that quite a company of these gentlemen have gathered about us. The amount of business they find is remarkable. Their tents are thronged from morning to night, and "while the day lasteth" their golden harvest runs on. Here, for instance, near General Burnside's headquarters, are the combined establishments of two brothers from Pennsylvania, who rejoice in the wonderful name Bergstresser. They have followed the army for more than a year, and taken, the Lord only knows, how many thousand portraits. In one day since they came here they took in one of the galleries, so I am told, 160 odd pictures at one dollar (on which the net profit is probably ninety-five cents each). If anybody knows an easier and better way of making money than that, the public would know it.

To Correspondents.

B.—There are several modes of producing enamel photographs on china, some of which are secrets and others patents. The process of M. Joubert has repeatedly been described in our columns, and is patented. It consists in coating the china or glass with a mixture of honey, albumen, and a bichromate, exposing under a transparent positive, coating with an enamel powder, and burning in the image. The process of M. Camarac has not been stated in detail so far as we know: we believe it consists in producing a transparent positive on a collodion film, either direct upon the china, or by transfer from a glass plate; toning this with gold, and then burning-in. We do not think the latter is patented in this country.

A. R. P.—Two ounces of hyposulphite of soda ought to be sufficient to tone two batches of 40 card portraits, provided they are well washed and the hypo is kept neutral. 2. Grey tones, if you desire them, may be produced by the aid of almost any of the toning formulas, by making them strong enough and toning long enough. With some samples of highly albumenized paper, however, it is very difficult to get beyond tints of purple brown. 3. There may be a limit to the time an exciting bath ought to be used even if the strength were kept up, as it is constantly receiving some

foreign matter from the albumen, and some aggregation of nitrates; but we have not noticed any deterioration, when the strength was maintained, in our own case.

J. K.—The price of Colonel James's work on photozincography is 12s. 6d.; it is necessarily a somewhat high-priced work, having several photolithographic illustrations.

T. W. S., Cambridge.—Any good bromo-iodized collodion will answer for the honey and tannin process; but we cannot with certainty recommend any commercial sample. It should not contain less than one grain of bromide to the ounce, and might, without disadvantage, contain more.

Y. Z.—The lens you name may be used for an enlargement of about four or five diameters, with a moderate stop, without impropriety; but the No. 1 triple lens is best for the purpose. Report on your glass in our next.

L. SHAW.—Your prints are promising. Many of your difficulties will disappear with practice. The spot on the shoulder appears to have arisen from an air-bubble or other similar cause having prevented the perfect action of the toning bath at that spot, and thus left it browner than the remainder. The toning bath with gold and acetate of soda is a very good one. If you have any special difficulties please state them specifically.

CALICO.—The formula of Messrs. Fordos and Gelis appears very satisfactory. Chloride of calcium is altogether a different salt to chloride, or hypochlorite, of lime, and must not be substituted for the other. 2. The exact action of acetate of soda in a toning bath is somewhat uncertain, and the formula not less so; the chief thing that is known on the subject is, that, practically, it gives good results. Samples of chloride vary in acidity, and samples of acetate of soda, which should be neutral, are some faintly acid and some slightly alkaline; generally, however, the latter. Wherever we have any reason to fear a trace of acidity in the toning bath we place the prints in a weak solution of carbonate of soda before fixing. This is a very safe practice, and permits the use of the gold bath if even faintly acid. A bath of gold, quite neutralized with carbonate of soda, will tone very well without any other addition. 3. We will try the intensifying process with a bromide. We cannot give any opinion *a priori* as to whether the results will be more stable than those of the iodide.

GILCHRIST.—The best enlarging lens is the triple; but a good portrait lens, say a quarter-plate, may be used for the amount of enlarging you propose.

CUDDE LUGES.—You have quite misunderstood us. There have been copyright acts in force for the protection of engravings ever since 1735. We believe the term of protection is twenty-eight years, and, therefore, all engravings published within that period, which have complied with the provisions of the law, are copyright, and may not be copied. 2. In filling up the office form for registering photographs you may place more than one picture in the form, but you must pay the fee upon each picture. 3. We have not seen any of the prints to which you refer, and cannot offer an opinion thereon.

EXCELSIOR.—Your glass is too brown, not the true silver-flashed tint. It lets some active rays through, but very few, and could be used with safety except in a very bright light. We may here give a word of advice to those of our readers who may require to send us samples of glass for examination. It will save some disappointment and trouble, if, in obtaining a sample of glass from a dealer, it be ascertained at the same time that he has a sufficient stock of the same sample on hand. Many dealers think they are quite near enough if they supply something which they conceive to be similar in tint, but which really may be altogether different in its power of repelling chemical rays. It is also important to secure, if possible, the silver-flashed glass, which generally has a somewhat mottled effect, as though it were stippled rather than stained.

AMATEUR DRY PLATE.—Almost all photographic materials, which come under the general head of "Chemicals," keep, if properly stored. Nitrate of silver, hyposulphite of soda, acetic acid, pyrogallic acid, gallic acid, chloride of gold, acetate of soda, &c., if kept dry and air-tight, keeps almost indefinitely. Plain collodion, cadmium-iodized collodion, and good bromo-iodized collodion will keep a long time—at least a year, if kept with any care; as will also iodized paper. Albumenized paper is best used as fresh as convenient, and will injure in a few months, if at all damp. Sensitive plates, or paper, should be kept dry and air-tight, but in most cases there is a tendency to deteriorate. 2. Mr. Bartholomew has given tolerably full details of his morphine process in our pages; but he will, doubtless, have pleasure in supplying more details on the points you wish, namely, the length of exposure, as compared with wet plates; whether an iron developer be necessary; whether acetate of morphine may be used in place of nitrate, and the proportion; whether any preliminary coating be necessary, and what is the best. 3. We cannot tell you much of the probable value of negatives of foreign landscapes. You will best ascertain by writing to some of the photographic publishers in this country.

CHARLES DERBY.—We have delayed publishing your description of a photometer, until we had more time to examine it carefully, as it does not appear very explicit. We certainly should not recommend you to patent it. We never undertake the duty of attending to patents, and did not understand you as making any inquiry about the subject.

J. B., Scarborough.—If you take the portrait of any person on your own account, with a view to publication, no agreement is required to permit you to secure the copyright. You execute the work for yourself, and it is yours. But if you take the portrait for the sitter himself, or for some one else, it being, as the Act phrases it, "a commission," then an agreement in writing is necessary. If the commission were for the sitter himself, and he be dead, then the agreement must be with his heir, who is his legal representative, can give you the proper permission in writing. We do not charge any fee for advice; but the claims upon our time prevent us writing private letters on subjects which can be answered in this column, where the information can also be of use to others.

T. R.—We do not know of any certain method in which old manuscripts can be copied by simple pressure.

Several Correspondents in our next.

PHOTOGRAPHIC SOIREES.

A VERY successful soirée of the London Photographic Society was held on Friday evening last, at the Gallery of British Artists, in Suffolk Street, where the exhibition of photographs is now held. A brilliant company, including many persons of distinction, thronged the rooms, examining the excellent display of pictures until a late hour.

We call the especial attention of our readers to a copious report, on another page, of a very brilliant soirée, held by the Glasgow Photographic Association. Indefatigable efforts had been made to secure a first-rate collection of photographs for exhibition; very able and interesting speeches were delivered, various photographic illustrations and experiments made, amongst which the erowing one was the production, by the aid of the electric light, of a portrait negative; Mr. Jabez Hughes, whose name is well known to our readers, being the sitter.

From this a transparency was immediately produced, and, in the course of a few minutes, the portrait was perfected on to the screen of the magic lantern, and shown, amid much enthusiasm, to the entire audience. We commend the account of this soirée to photographers, because it exhibits an amount of energy, unity, and enthusiasm among photographers, rarely witnessed, but worthy of all emulation.

ON A PROCESS FOR DIRECT INTENSIFYING.

M. BLANQUART EVRARD has addressed the following communication to the Paris Photographic Society and recorded in the *Bulletin*.

It has for a long time been known that when a sensitized surface is exposed to light, after it has been impregnated with a reducing salt in solution, we obtain, upon removal from the camera, a completely developed image.

In ordinary practice, in which the sensitized film only is exposed in the camera, the image obtained by the exposure remains latent until revealed by a reducing solution.

Three agents, therefore, concur to produce the image.

1. A sensitized film (sensitized collodion.)
2. Light.
3. A developing salt. (Sulphate of iron, gallic and pyrogallac acid.)

I shall not occupy myself in this place either with the sensitive film or with the reducing salts whose action varies; the sulphate of iron precipitates the silver in the metallic state; the gallic and pyrogallac acids form with silver, in my opinion, gallates of silver more or less coloured;—but I shall examine the action of light, from which it seems to me possible to derive a new resource under certain circumstances.

It is admitted that there is a complete formation of the image by the exposure to light, however short may have been its duration. We may then infer that if the image does not entirely appear under the action of the reducing

salt, it is because the latter is not sufficiently subtle. It remains, then, to find a reducing salt capable of revealing the image in all its strength.

But has the sensitive film itself been so deeply impressed as to be able to transmit afterwards the image in its entirety?

From what occurs in ordinary practice, we may be allowed to doubt if it does.

When the exposure has been too short, the image is formed only on the surface of the film. It results from this, that the layer of reduced silver has not sufficient thickness to oppose a sufficient obstacle to the passage of light. In taking the positive, we obtain only a pale and ineffective design. If, on the contrary, the exposure has been too long, the reverse action is produced, the parts most lighted assume too great an importance. The details in the lights disappear, in compensation we obtain details in the shadows which a short exposure would not have given, but the picture is none the less poor and inharmonious. The negative is lost.

The point at which we must stop the exposure is then very difficult to seize upon. There is an equilibrium to be preserved, which becomes impossible under certain conditions of lighting and colour.

We employ, it is true, different means to give either more importance to certain parts of a negative, or to diminish the value of certain others, but these partial intensifyings, by means which I am almost tempted to call mechanical, are almost always defective.

Thus far, then, we have actually acquired the possibility of intensifying a negative as a whole, and still the means employed are hazardous, and very often compromise its existence by causing a softening of the collodion, wrinkles, rents, &c. Besides, it seldom happens that a successful intensifying does not cause the image to lose a portion of its primitive delicacy.

For the chemical means hitherto employed we must substitute a more inoffensive method, so as to develop any portion of the image at pleasure, by localizing the operation, either by too short an exposure, or that the colouring of certain objects adverse to the photogenic action be suitably modified.

This method will be *the continuation, under certain conditions, of the action of light upon the sensitive film*, or, in other terms, *the light completes the manifestation of the image formed in the camera*. I sum up the principles upon which my theory is based.

On removal from the camera, the image in its entirety is imprinted on the sensitive film. The impression is more or less decided, according to the duration of the exposure or the intensity of the light.

The image is visible only after being developed by the reducing agent, and it is not till then that we can judge its value.

However, if before developing the image we assume that the exposure has been insufficient, and that we desire to augment it, we have only to remove the cap from before the

objective, the impression continues, nothing being changed in the chemical condition of the sensitive film.

Query: would it be the same if we re-exposed the image after it has been precipitated by the reducing agent?

A priori, we reply, No! Nevertheless experience has shown me that if, upon removal from the camera, we develop the image by the gallic acids or sulphate of iron, and that after having washed the negative simply in water, we expose it to the light, the image strengthens more and more, it may even attain to an astonishing vigour.

To account for this phenomenon, and explain why the image does not become a black mass, as happens when we treat a paper negative in the same manner, we must consider that in a collodion glass plate the surface only is impregnated, and that the reducing salt which precipitates the image removes at the same time all the silver which has not been impressed, and is carried away with it by the washing in water. There remains, then, on the negative no other silver upon which the light can act beside that which forms the image.

We can readily understand that it is different with a paper negative. The washing in water clears only the surface. The interior of the paper retains a quantity of silver which is impressionable by light so long as it is not dissolved in the hyposulphite.

How does light continue the development of the image? Does the metal pass to a higher state of oxidation? Is a thicker film precipitated? It is certain that the opacity of the image sensibly increases. Positives obtained in the first and second states of the negatives exhibit very striking differences.

The atmosphere plays an important part in the action produced. If we preserve a portion of the image from contact with the air, and cover it with a transparent varnish which permits the light to pass, the part covered with varnish becomes only feebly coloured, while the remainder sensibly deepens in tone, we must, therefore, admit that there is a greater oxidation of the metal.

As to the precipitation of a thicker metallic film—for this to take place it is necessary that the first exposure in the camera has impressed more of the sensitive salt than the reducing salt can precipitate; there will then be an incomplete reduction of a portion of the silver, a reduction sufficient to prevent its being carried off by the water in washing, but susceptible of being continued and completed by a second exposure. I admit this more readily from what takes place when, if after washing, the negative be fixed by hyposulphite of soda, and afterwards exposed to the light, we no longer obtain an intensifying of the image, the hyposulphite having dissolved all the iodide of silver not completely impressed by the light.

Whatever the theory I humbly submit to the appreciation of the eminent chemists to whom you refer questions of this sort, it has always appeared to me

That it is possible to strengthen a collodion negative, by exposure to light alone, after simply washing in water, on removal from the developing bath.

That we can follow with the eye the progress of the operation, and stop it at will by irrevocably fixing the image with hyposulphite of soda.

That we can also localize the action of light by exposing to its contact only a portion of the image, and thus obtain a partial intensifying.

To arrive at this interesting result, we must, by means of screens suitably placed, so as not to form gaps in the image, merely obscure those parts of the object which may be considered as being fully impressed. In this manner we can strengthen at will any portion of an image just as the engraver in mezzotinto lights his plate by means of a burnisher.

Note.—If, to carry the comparison with the work of the engraver still further, we wish to obtain the reverse effect, that is to say, darken the parts which are too light, and give more depth to the shadows of a negative, we must

diminish the opacity, or thickness, of the film of reduced silver. We arrive at this result by submitting these portions to the action of the vapour of iodine. These vapours combine with the silver forming, at the expense of its thickness, an iodide of silver, which dissolves in hyposulphite of soda.

PHOTOGRAPHIC EXHIBITION.

FIFTH NOTICE.

As the last week of the exhibition approaches, and it is now open in the evenings, as well as during the day, we hope those of our readers, who can, will make the most of the remaining opportunities of examining the contributions.

We have not hitherto given much attention to the portraits exhibited, chiefly because a very large number of them had been already exhibited in the International Exhibition. We will now, however, briefly glance at such pictures as have chiefly attracted our attention. The two portraits, which have, perhaps, excited more interest than any others in the exhibition, are those of Alfred Tennyson and Thomas Carlyle, both by W. Jeffreys. These, apart from the distinguished character of the men, although only half-plate pictures, are as admirable specimens of portraiture as any in the exhibition. Characteristic in pose, round, soft, and full of half-tone, yet very vigorous and forcible; they are altogether exceedingly fine photographs. The grim power of the Chelsea philosopher, and the lofty thought of the laureate, are well rendered in the pictures, and convey the impression at once that the portraits are characteristic of the men.

Mr. Claudet's portraits, to which the medal was awarded, are very numerous, and are scattered throughout the different rooms of the exhibition; they consist of *cartes de visite*, of various large-sized pictures, taken direct, and of solar camera pictures, plain and coloured. They all display many excellent qualities. Those we like best are the large pictures, taken direct from life, of which, No. 116, a portrait of a lady, in a light dress, is a fine example. Some of the enlarged pictures are also very fine.

The solar camera pictures, of Mr. Stuart, we have before fully described. We need only remark here that, being hung amongst several brilliantly-coloured pictures, they are seen to less advantage than when examined alone, as they lose brilliancy by contrast with the amount of colour surrounding them.

An untouched solar camera picture of Herr Formes (563) exhibited by Mr. McAndrew, looks grey, flat, and poor. It is unfortunate that solar camera pictures so often run to extremes. If they are soft they are flat and feeble; if vigorous, they are coarse and hard. Mr. McAndrew's other contributions are for the most part very excellent, and comprise some excellent specimens of large untouched portraiture.

Mr. T. R. Williams sends a fine selection of his charming vignettes of rare beauty and delicacy, both whole plates and card pictures, of which, however, we prefer the larger size. Mr. Mayland, of Cambridge, sends a frame of albumen portraits (655), so nearly resembling those of Mr. Williams in style, and nearly equalling them in quality, that we have heard them frequently mistaken for those of the latter gentleman. This we consider almost the highest praise they could receive. Mr. Mayland's card pictures (654) are equal to any in the exhibition.

Mr. Robinson sends a small frame of his exquisite card portraits (653), which are unfortunately hung too high for careful examination. Two or three of the groups in this frame we consider the finest card pictures ever issued. A standing group of two pretty girls at the entrance of an arbour is especially worthy of notice.

A frame of 10 by 8 pictures (589) exhibited by Mr. Carrick, presents some lamentable instances of what to avoid in careful examination, and fills us with regret. Mr. Carrick is a miniature painter of no mean standing; and in many respects the portraiture and photography both are good; but

the backgrounds are so "loud" that it is next to impossible to see the portraits; the objects in the painted background will obtrude themselves, and the whole effect is one of extreme confusion. To use the remark of a foreign gentleman who examined them, they looked "very much troubled." There is one exception to the remark amongst Mr. Carrick's pictures. In this (690), a lady is standing in a room, her face apparently lighted from an open door, and in this case the effect of the flood of light on the objects in the interior is very pleasing.

Mr. Joubert exhibits some very fine cards. Mr. Mullins, of Jersey sends some very charming card pictures of the same class, and Mr. Brooks, of Newberry, sends a frame of cards which are interesting as specimens of double printing.

Mr. Cooper contributes a good selection of examples of resin printing, many of which are also very charming photographs. Artistic in feeling, soft, and delicate, as well as brilliant, they are admirably fitted to recommend the use of resinized paper for very many purposes. In these, as also in the exquisite specimens of Mr. Cooper on silk, the system of double or fancy printing, is applied with excellent taste.

Hennah and Kent send some very fine portraits, which, if they do not maintain the pre-eminence in portraiture they once possessed, yield that position, not from any lack of excellence of their own, but from the gradual progress of others up to a similar standard.

Some exceedingly perfect specimens of portraiture, by Angerer, of Vienna, are not numbered, but they should not be overlooked by visitors interested in this branch of the art. There are four other unnumbered portraits to which we would call especial attention: they are hung in the door-way leading into the room containing French contributions. These are by Dr. Diamond, and will interest photographers not only as far surpassing any other specimens of amateur portraiture, but as equalling the best to be found in this exhibition, both as artistic and characteristic portraits, and as perfect photographs.

Associated closely with portraiture are life-studies, of which, whilst there are not very many in this exhibition, there are a few gems. We have before referred to the studies of Viscountess Hawarden, and which, very properly, we think, gained the medal as the best amateur contribution. There is a wonderful charm of freshness about these pictures which is much less common in photographs than we like to confess. These consist for the most part of female figures with interior accessories: there is much grace and beauty both in the fair models themselves, and in the posing and general arrangement, but the chief charm consists in the daring lighting and the artistic effects of light and shade secured. There are figures brought close to the window of a room into which pours broad sunlight: the portions tipped with the bright light are full of detail and free from chalkiness, and the masses in deep shadow are perfectly transparent and free from blackness. In some cases a portion of the window, balcony, and objects beyond is included, and these have sufficient detail to be compatible with atmosphere and distance. In some cases the effect of light reminds of some of Rembrandt's pictures, in which one bright light is in strong contrast with a mass of shadow into which, however, the light is sufficiently carried to secure both transparency and breadth. We regard these pictures as most instructive and well worthy of study as illustrations of lighting of the effects possible in photography. They are produced we understand with a highly bromized collodion: a very strong iron developer, sometimes containing as much as fifty grains of iron to the ounce, and with Dallmeyer's No. 1 Triple lens, which secures this wondrous depth of definition. Should these studies be published, and we believe we may venture to hope they will be, Lady Hawarden, having, we believe, given her consent, we should recommend every portrait photographer to possess and study them.

Mr. Rejlander has not contributed many of his fine art photographs to this exhibition; we find however, two very

charming studies, Nos. 567 and 574. The first is one of those genuine touches of humour in which Mr. Rejlander is so happy, and is entitled, "Give us a copper, yer honour." A comical, ragged urchin with broom in one hand, and the other touching his cap, is trotting along evidently in front of some one, to whom he turns his head and looks up; his face wears a droll, coaxing expression, as he begs the copper he has earned by sweeping the crossing. The second picture is a beautiful head surrounded with white drapery, arranged somewhat after the fashion of a nun; the general effect being after the Madonna of Sassoferata. The expression and general treatment are very beautiful, the whole of the face being in a mezzo-tint, with an exquisitely transparent and delicate shadow on the forehead, cast by the projecting drapery. Altogether it is one of those rare gems seldom obtained by photography.

Besides these and some before noticed, there are not many figure studies. There is a picture by J. J. Keet, entitled, "The Lost Game," which does not convey any especial idea beyond two persons playing a game of chess; and a couple by J. T. Lucas; one, "Hard Times," the interior of a Lancashire cottage with its inmates; and another, "The Maid of Llangollen." The first of these is best, and has many fine points; the second is hard as a photograph, and a little wanting in reason for its title.

The coloured portraiture strikes us as a mistake; very much of it here is staring, vulgar, and coarse, with little of photography, and nothing of art. Some garish looking solar camera pictures coloured in pastels, are particularly offensive, in their hard, crude, raw colour, glaring without brilliancy, and suggesting nothing but chalk. The great evil of these things is, that while nothing of photography remains, being overlaid by the stiff drawing of the painter, the glaring colour spoils the eye for the quiet monochrome of the pure photographs which are near them. The best pictures here are those coloured in oil, of which some are exhibited by M. Claudet, which are really well coloured. Some portraits painted by M. De La Folie, and exhibited by Mr. Mc Andrew, possess great truth and purity of colour, with much force and brilliancy. No. 508 is a good example; No. 510, a portrait of a lady, is well coloured, but badly posed. Nos. 519, 539, 543, and 551, coloured by this gentleman, are all exceedingly good, the flesh being healthy and pure. The life size portrait of Mr. Chance of Birmingham, exhibited by M. Claudet, and that of Lord Brougham, exhibited by Mr. Mayall, are both fine. Mr. Brothers exhibits some fine composition groups, and one of the chief savans at the Manchester meeting of the British Association is well coloured in oil. Mr. Wall exhibits a large head coloured in oil, which has many good points, but he can paint better than this. There are many more coloured pictures, some of which are not worthy of notice, some moderately good, and many in regard to which silence is the best praise which can be awarded them.

Critical Notices.

PRACTICAL PHOTOGRAPHY ON GLASS AND PAPER. Fifth Edition. London: Bland and Co., Fleet Street.

THE especial claim to notice of a fifth edition of this little work is the fact that it is entirely re-written, and becomes practically a new book. Notwithstanding the fact that it has obtained a very wide circulation in its original form, not less than twenty thousand copies, we are informed, having been issued, the publisher recognizing the vast advancement made during late years, has felt it important that a book, for beginners, should contain instructions for the best and most approved practice of the art, so far as it is known at the present time, instead of the teachings written eight years ago, many of which must now be obsolete. The design of the work has also, it appears, become more comprehensive

a second part being produced, which is to deal with those branches of photography chiefly interesting to the advanced student, while the first part—that now before us—is chiefly elementary, and is confined to the wet collodion process, and to printing.

The style of the book is very simple and lucid: the student is not perplexed with discussions as to his various theories propounded; but is conducted by easy and sure steps into the practice of the art. An introductory chapter contains a brief statement of principles, and such an explanation of distinctive technicalities as may render clear and easy of comprehension the instructions which follow. They comprise the production of positives on glass, of collodion negatives, and of printing on plain and albumenized paper. There are also chapters on tinting positives on glass and paper; on the production of stereoscopic pictures; on imperfections and failures; and also one which will render the work valuable for calculation in many of the colonies, on photography in the tropics.

So far as we have examined the work, the instructions are always sound, as well as lucid and clear; and such as, if followed, will ensure successful results. A number of excellent wood engravings, illustrating modes of manipulation, as well as forms of apparatus, materially add to the interest of the book, which, as a whole, we can cordially recommend as one of the most simple, clear, and trustworthy instruction books we have seen.

THE COMIC ADVENTURES OF A YOUNG MAN FROM THE COUNTRY. Photographed by Dages and Harman, from designs by Percy Cruikshank. London: Ward and Lock.

THE claim which this little work has to the especial attention of photographers consists in the fact that photography has here taken a place very commonly assigned to lithography, being applied to the reproduction of a series of original sketches. It is unnecessary for us to trace the career of the "young man from the country, who thought no one could get over him on his way to visit the International Exhibition, and who went back without seeing it," beyond remarking that the designs possess some humour, but are a little wanting in delicacy. The photography is, however, unexceptionable, the prints being scarcely distinguishable from Indian ink drawings. They are chiefly on plain paper, and are printed with a margin, so as to avoid the evil of the book bulging and gaping from the accumulated thickness of the mounted photographs—an evil sometimes very annoying in other cases where photographs have been used for book illustration.

COLLODION, WET AND DRY.

BY M. L'ABBE DESPRATZ.*

Various Reactions.—It now remains to add some practical developments of the ideas we have suggested in our preceding article upon the sulphate of iron developer. First remarking, however, that the various methods we have successively described, are principally applicable in making use of a sensitizing bath, which, if not new, had been but little used. For, with an old bath containing a considerable proportion of alcohol and ether removed from the collodion film, the development of the image is not always made with the wished-for regularity; and, in that case, the success which we announced as infallible becomes, in some measure, exceptional. Yet still, even with a very old silver bath, and containing a strong proportion of alcohol and ether, a perfect result may also be obtained by developing with sulphate of iron as concentrated as possible; only in this particular instance, which most frequently becomes general, we must have recourse to a special manipulation, which we now proceed to describe carefully.

First, a word upon the preparation of a good sulphate of iron bath. In a quart of rain or distilled water dissolve to

saturation, cold, some pure sulphate of iron. The solution will be saturated when some crystals remain undissolved. If the sulphate be really pure, the solution will be at once fit for use. If commercial sulphate of iron be used, which frequently contains free sulphuric acid, and very often some sulphate of deutoxide of copper, we must drop into the solution some Paris white, which will decompose this latter salt, and also neutralise the sulphuric acid in excess. It is then left four and twenty hours to settle. The bottle containing the solution should be kept always full, by the addition of a quantity of the mixture of sulphate and water equal to that used.

As we may perceive, this bath is very easily prepared; but we have never allowed ourselves to believe that it was necessary to complicate it by the addition of alcohol or any acid whatever, and still less to greatly reduce its strength. There may, it is true, be very plausible reasons given for having recourse to these additions; but we believe it is most advantageous to do without them altogether. What, for instance, are the reasons given for the addition to the sulphate of iron, of either alcohol, acetic acid, or even sulphuric acid? Doubtless they have been recommended with a view of putting the iron bath in harmony with the silver bath, if not in a chemical point of view, at least in a physical. For the sensitizing bath containing alcohol, ether, or even acetic acid, experiences a kind of repulsion for the bath of pure sulphate, with which it mixes only with difficulty. An acid added to the iron bath, and particularly alcohol, destroys this mutual repulsion and changes it into a real affinity: but this advantage can be obtained only at the expense of energy in the developer, which is not a trifling inconvenience.

With the employment of the mode of operating which we wish to see adopted, this inconvenience no longer exists, for the pure and concentrated iron bath retains not only all the energy, which by this quality is peculiar to it, but also works with all the desired regularity, even with a sensitizing bath highly charged with alcohol and ether.

The alcohol and ether of a bath become old by use; being the only obstacle to the regular action of the bath of pure concentrated solution of sulphate of iron, it would seem natural that, to cause it to disappear, it would only be necessary to warm the bath. The heat ought, in fact, to expel these two fluids. This method has been pointed out, but we have not had recourse to it; it seems to us too radical, if not suicidal. A bath which has become good by use is a thing too precious to allow us to decide upon submitting it to so violent a torment, exercised upon principles as yet but little known, and the association of which is, moreover, full of mystery. We preserve, therefore, the bath just as *nature* has made it; but if, to sensitize the plate, we leave it its alcohol and ether, there is no objection to removing them from the collodion film when it has been impressed by light, which we effect in the following manner.

The plate on being removed from the camera obscura is placed flat on the bottom of a dish containing sufficient rain or distilled water to cover it completely.

We then give a rocking motion to the dish, and continue it until the water flows freely over the film, which it does as soon as the greasy aspect disappears. The plate is next placed on the tripod, levelled, and covered with a weak solution of nitrate of silver (strength two per cent.), and this is allowed to act for a minute at most. At the expiration of this time we lift the plate and pour off the silver solution into a beaked measure, and allow the plate to drain thoroughly. Meanwhile, we have ready a flat bottomed dish containing the concentrated solution of sulphate of iron, to the depth of half an inch. Holding the plate by one corner, we place it vertically upon the bottom of the dish, and *at the same moment* drop it, by means of a hook, into the iron solution without the slightest hesitation or pause: it must be allowed to remain two or three seconds and then lifted out; if it has been exposed the right time, the image will appear with all its details.

* Continued from Vol. VI, p. 464.

It will also be understood, that if the concentrated bath possesses sufficient energy to cause all the details of the image thus to appear instantaneously, the proportion of silver is too feeble to give the desired intensity of tone. A new dose of silver must now be made to react upon the free sulphate of iron which covers the plate. To this end, the plate being partially drained, is again placed on the tripod, and inclined at a certain angle, and by the opposite corner pour quickly over it the silver solution reserved in the beaked measure. The silver solution must be made to flow over the plate as quickly and as evenly as possible, and repeatedly during several seconds, in order to facilitate and equalise the reaction. Immediately the blacks, which were very feeble, become strengthened in an extraordinary degree, and all the details gradually appear. In this case, the action is not instantaneous; we can continue it during three or four seconds, and it very seldom happens after the expiration of this lapse of time that the development is incomplete. However, if we wish for a still greater intensity of tone, we can drain the plate again, submit it for the second time to the developing bath, and a third time to the silver solution, and so on until the contrasts between the blacks and whites is satisfactory. But, we repeat, if the time of exposure has not been unreasonably short, and if the sensitizing bath be quite neutral, a first strengthening of the image will generally be found sufficient.

In the case where, by insufficient exposure, the negative remains weak, we can repeat several times the methodical strengthening with sulphate of iron and nitrate of silver, without exposing the picture to the thickening too frequently observed when employing pyrogallie acid; only, as the film too feebly impressed by light in the camera has not sufficient strength to retain the silver decomposed by the sulphate, it forms a pulverulent deposit which, by its mechanical adherence to the film, opposes itself to the ulterior electrical deposit, the only one capable of forming the image. In these conditions the defects of the photographic impression are manifested by a crowd of little white or grey points. We may avoid this defect by first filtering the iron bath, and also by washing the plate in pure water, in order to free it from every mechanical deposit, before submitting it to the two per cent. silver solution. If we have care to take these precautions for cleanliness at each alteration of the silver and iron solutions, it will very often be possible to bring out a good picture from an under-exposed plate, which at first we might have despaired of.

The electrical action in photogenic phenomena, of which we have spoken in a preceding article, appears to us particularly evident during the development with sulphate of iron. Upon the decomposition of the nitrate of silver by this metallic salt, an electrical current is established, possessing very great energy, which ceases immediately the decomposition is accomplished. By the effect of the imperfect conductivity of the bodies brought into contact, the duration of this decomposition is appreciable, and it is during this interval that the silver carried by its excess of electricity fixes itself upon the impressed iodide. This free electricity of the silver reacts upon the natural electricity of the iodide, or, rather, it combines with the opposite electricity of this body, rendered free by the action of light. Whatever it be, some molecules of silver, however attenuated, would never fix themselves upon the iodide of the film if they were not solicited on their own excess of free electricity; what proves this is, that upon the appearance of the image through the action of the sulphate of iron, there is a considerable excess of silver reduced, while a very minimum quantity is retained by the plate; only that which is in contact with the iodide impressed by light, the remainder, which is found outside the sphere of the electrical activity of the iodide remains in the bath, where its electricity is dissipated. If, therefore, we desire a new deposit of silver to take place, a fresh quantity of electricity must be disengaged, and this we always obtain when practising the artifice of strengthening as we have described it.

(To be continued.)

NEW PROCESS FOR POSITIVE PRINTING.

BY M. BERTRAND.*

This process does not differ in principle from that in ordinary use with chloride of silver. It consists, likewise, in impregnating the paper with a soluble chloride, which is transformed into chloride of silver, in exposing a paper thus prepared beneath a negative, and in fixing and toning. I do not enter into lengthy details, as the manipulations are nearly all the same as in the ordinary process.

I prefer the *papier de Saxe*; evenness of substance is not absolutely necessary, but sheets having spots of iron must be rejected.

The first preparation of the paper consists in impregnating it with a soluble chloride: it is immersed or floated in the following solution.

Alcohol (36°)	100 parts
Benzoin	10 "
Chloride of calcium	5 "

The most expeditious method consists in taking a dozen sheets of paper, and immersing them one by one in the bath, with the aid of a glass rod; when a certain quantity is immersed they are all turned in a heap, and withdrawn one by one, then hung up to dry.

The improvement effected by the benzoin consists in completely stopping the pores of the paper: air and moisture can no longer penetrate the proofs, which are thus protected from the principal, if not the only source of deterioration. The benzoin also imparts the gloss of albumen to the paper, but in a less degree.

This chlorided paper will keep a long time; it is sensitized by being placed in contact with the following bath.

Water	100 parts
Nitrate of silver	15 "

If it is desired to keep the sensitized paper a long time, it must be placed in a box with chloride of calcium.

The exposure under a negative is shorter than with albumenized paper: the proof is printed deeper than required ultimately. If the exposure is continued a long time, the blacks become dark green, but this need give no concern, as the toning bath restores the blacks.

For toning I employ M. Bayard's formula.

Water	1000 parts
Chloride of gold	1 "
Sal Ammoniac	20 "
Hyposulphite of soda	4 "

Or the acetate bath:

Water	1000 parts
Chloride of gold	1 "
Acetate of soda	30 "

Or any other toning bath.

The proofs rapidly assume a black tone, which is obtained with difficulty on albumenized paper.

They are fixed in

Water	100 parts
Hyposulphite of soda	20 "

When the proofs are well washed they are left to dry, then rubbed with a tuft of cotton wool, or a piece of flannel, to impart lustre. It must evidently be useless to varnish them.

—*Bulletin de la Société Française de Photographie.*

GLASGOW PHOTOGRAPHIC ASSOCIATION.

GRAND SOIREE, EXHIBITION, AND CONVERSAZIONE.

[FROM OUR OWN CORRESPONDENT.]

THE above interesting and long looked-for Soirée took place on Feb. 19th, under the auspices of the Council of the Association, in the Merchants' Hall: about 400 members and friends

* M. Bertrand first published his process in Paris, just prior to the publication of Mr. Cooper's; both gentlemen having been apparently experimenting in parallel directions. We should, however, recommend Mr. Cooper's last improved formula as the best.

assembled, but had the hall been able to accommodate twice the number, it is probable that it would have been filled, the demand for tickets being so great; but the Council deemed it better to limit the number to as many as could be comfortably accommodated. It would be well if this example were more often followed, for the practice is too general of issuing twice as many tickets as there is accommodation for, and the crush and squeezing often entirely spoils the pleasure of the meeting.

The handsome hall was decorated with an extensive and choice collection of photographs by the most celebrated artists of England and Scotland, also a quantity of apparatus contributed by Dahmeyer, Ross and other distinguished makers.

The meeting was presided over by Professor Allen Thomson, M. D., F.R.S., who was supported on the platform by Dr. Taylor, Dr. Penny, Dr. Rainy, Professor Wallace, Professor Blackburn, Jabez Hughes, Esq. (of London), E. Braze, Esq., A. Maetear, Esq., J. Stuart, Esq., A. Macnab, Esq., J. Jex Long, Esq., J. Spencer, Esq., and other gentlemen.

The proceedings of the evening commenced with a bountiful service of tea and coffee, an efficient band of music meanwhile enlivening the company with popular quadrilles, and operatic selections. Tea concluded.

The CHAIRMAN, Dr. Allen Thomson, apologized for the unavoidable absence of the President, and congratulated the association on their excellent attendance and splendid display, and trusted they would heartily enjoy themselves. He maintained that that association represented one of the "Wonders of the Age"—Photography. It was an art as remarkable for its rapid rise and progress as for the deep and subtle scientific principles on which it was based. It had arisen, not only in our own time, but almost under the eyes of the youngest amongst us. But a few years since, it was the latest marvel of science, and now it was practised everywhere. The early examples of the art were costly and imperfect, obtainable only by persons of means; its progress, however, had been marked by a series of rapid strides, and each step of progress has not only improved, but cheapened it; so that now, in its highest degree of perfection, it was within the reach of all. Thus had this philosophical wonder become almost a daily necessity, and, ministering to our feelings and affections, it was equally appreciated and patronized by the highest and the humblest in the land. He continued:

There is a combination of science and art—of fine art and the highest taste—that secures approval for photography wherever it goes, and makes it one of the most delightful occupations that can be followed. I think it may be viewed in various aspects. I take first that which suggests itself the most readily to the mind and heart, its social aspect. Where is the house you enter now that you do not find portraits of beloved friends and valued scenes, remembrances of every description by the photographic art? Who is there now who has not his large album of cartes de visite, or his small and cherished collection? A friend of mine gave me an illustration of this the other day. He met an old woman, and he asked her about her children. "Where," said he, "is Maggie, where is Betty, and where is Tom, and so on?" Well, he got an account of them all. Tom was gone to Australia; Maggie was married, and gone to Canada; and Betty was gone to New Zealand. "But," said the old woman, "here they are all in my pocket." (Laughter.) "I will show you their husbands, and Tom's wife and bairns, and I have got pictures of the cottage which they have just built, and the place is beautiful." This is a simple picture of what occurs in almost every family of the present day. I say it is a picture of the social aspect of this art of the most agreeable and delightful description. (Applause.)

The Chairman then alluded to the general improvement in taste, and this he attributed to a considerable extent to the influence of photography. No doubt such great Exhibitions as those of 1851 and 1862 produced powerful influence, but to this art must the greater effect be due, and no more striking proof could be given than the almost entire suppression of miniature painting, and the commoner form of oil painted portraits. These were avowedly ill-drawn, even when well painted, and at best unsatisfactory representations, and he had no hesitation in saying, that even an ordinary photograph of the present day, by virtue of its truthfulness and accuracy, stood higher as a work of art, and was of more real value to its possessor, than many of the costly and pretentious productions of days past. Some persons objected to photographic portraits because they did not make more pleasing likenesses; this he thought was more often attributed to the sitters themselves than photography, for it must be remembered that it was the person himself who pro-

duced the expression that was copied on the plate. He thought this subject was likely to engage the attention of the public more than it had done, as he found many persons who really did study the pose and expression, with the view to aid the artist and secure a better photograph. Still, for his part, he was a great advocate for truth, and if the frown was habitual on the brow, he did not see why it should not be on the photograph too. (Cheers.) It was to be regretted that doubts still existed as to the ultimate permanency of the prints. Yet as so much advance had been made, he doubted not that science would speedily solve this problem, and that the certain stability of the prints would be one of the earliest improvements recorded. Allusion was then made to the usefulness of photography in fostering and diffusing a taste for the fine arts by reproducing, for comparatively trifling sums, copies of the celebrated statues of antiquity, of the pictures of the best masters, of the choicest examples of the architecture of all lands, as well as some of the most beautiful and interesting scenes in Nature.

After alluding to the utility of photography in copying objects in natural history, historical monuments, rare manuscripts, &c., he enjoined the company not to neglect the opportunity of a close inspection of the exquisite works before them, as it might be long before they again had so favourable an occasion.

The band now performed a variety of popular airs and a choral party sang quartettes.

Mr. E. BRACE (Hon. Secretary to the association) delivered a very interesting address, in which, after alluding to the rise and progress of the art, he contrasted it twenty years ago, when practised only by Claudet and Beard, to its present diffusion, where almost every village has its professional artist.

He had been at some pains to collect a few statistics on the subject. He found by consulting the Directories, that in London there were 194 professional photographers; in Liverpool 51, Manchester 49, Glasgow 38, Edinburgh 33, and Aberdeen 15. He was aware that these figures very much understated the real numbers, as there were many photographers whose names were not in the Directory, yet even these showed that there were nearly 400 photographers in the three principal cities of England and Scotland. But this did not represent in any degree the number of persons employed; as, in every establishment there are several assistants.

In one establishment in London, there were last season nearly 100 hands engaged, and in many the number were over 50. He proposed to assume on an average, that there were ten assistants, this would show 4,000 persons employed. The wages earned varied considerably, according to skill and ability, but if each were paid £1 per week, this estimate would show that nearly a quarter of a million sterling was paid per annum as wages for photographic assistants. These figures, however, let it be understood, bear reference, not to the United Kingdom, but only to the three principal cities of England and Scotland, and therefore gave but a very imperfect sketch of the real number of persons employed in photography, or of its value as an industrial art. As an enormous quantity of gold and silver was consumed in the production of photographs, he had endeavoured to get an approximate idea of the amount. He had put himself into communication with two of the largest houses in the trade, and from the data supplied, he found that during 1862, there were 152,216 ounces of metallic silver consumed, nearly 4½ tons of the precious metal. So large an amount might be supposed to influence the currency, fortunately, as yet, it had not done so. This silver was converted into upwards of 240,000 ounces of nitrate.* He had endeavoured to form some idea of how many pictures could be produced by this amount of nitrate of silver. Here he entered more into the region of surmise, but he took it for granted, that, though a good deal of this nitrate of silver was consumed in the production of negatives, yet that the great proportion was employed in sensitizing the paper. He thought he was also justified in assuming, that during the past season the bulk of this nitrate was used in the production of cartes de visite. By a comparison of notes with an eminent photographic friend, based on the number of grains of nitrate of silver required to sensitize a whole sheet of paper, and the number of cartes de visite that could be produced by this whole sheet, he had come to the conclusion, making

* As Mr. Brace derived his data from two wholesale houses only, and as one of these is not by any means the largest manufacturer, it is probable that the amount is much understated. Perhaps 500,000 ounces of nitrate of silver would be a more accurate estimate, but allowance must be made for a considerable quantity of the precious metal that is recovered from cuttings and waste solutions.—Ed. P.N.

allowance for the small proportionate amount required to produce the negative, that each carte picture represented a grain of nitrate of silver consumed in its production. If, then, every grain of nitrate of silver represented a card picture, this amount of silver would show the enormous number of 105,441,129 pictures produced during 1862; and further, if one shilling be taken as the average paid for each of the pictures, it will be seen that photographers have received no less than £5,272,064 odd, for their productions during the past year. He also found from the data supplied by these two wholesale houses that, to improve the tone of their pictures, and give them increased permanence, photographers had consumed during the year past 3,000 ounces of metallic gold, which, at £30s. 6d. per ounce, represented £9,075. Although the conclusions he had drawn could only be regarded as approximate, yet they would show the enormous scale upon which this art was practised. This would also be established by the large sums that were allowed by the refiners for the clippings, cuttings, and waste solutions of some of the principal London photographers. He found that sums so large as £200, £300, and even £400 had been paid during the year for these waste products.

Mr. Brace then proceeded to call attention to the more remarkable pictures exhibited on the walls. There was first the large view of the Broomielaw by their President, Mr. Kibble. This picture was taken several years since, and the character it then held of being the largest photograph ever taken is still maintained, for no one had since taken a picture so large. The size of the negative was about 44 inches by 36 inches, and he was pleased to say it was as perfect as it was large. There were also many of Mr. Kibble's instantaneous views, which were most perfect examples of that branch of the art. There were also the exquisite landscapes of their townsman, Mr. Annan, which would bear advantageous comparison with the works of the best artists in that line. Attention should be given to two perfect pictures by a Glasgow amateur, Mr. Church, which had had prizes awarded to them in London for their excellence. They had also a beautiful winter scene; a prize picture, too, by the Earl of Caithness, who had shown in photography as in other branches of practical science. There were also excellent examples of the skill of their local artists, in coloured and other portraits, particularly the popular cartes de visite of Messrs. White, Douglas, Macnab, Stuart, Bowman, Alexander, and others. There is another department in which, considering the smoky, foggy, atmosphere of this city, we could never expect our artists to shine, and yet to Glasgow had been awarded the palm for excellence in solareamera pictures. On the walls they would see the productions of Mr. Stuart. Some of these were on exhibition now in London, and they had there been acknowledged to be unequalled. But unless, smoky Glasgow has more than one artist destined to shine in this branch. Since Mr. Stuart's works have been seen and admired, Mr. Douglas has also exhibited a solar picture; it is on the walls to-night for you to admire; and if this be but his first attempt, as I understand it is, considering the known skill and ability of the artist, I ask, what may we not hereafter expect from him? Among the strangers, they had some excellent Scotch views by Roger Fenton, scenes in Egypt and the Holy Land by Frith, Roman views by Macpherson, and Venetian by Ponti.

Mr. Brace then alluded to his own experience as an amateur; he had had much pleasure in practising this fascinating art, but he had too little time to devote to it. He had had his troubles and difficulties like all others, but whenever he got into a mess he had only to go to one of the professional brethren, who were always ready with advice and assistance. As an amateur, he tendered his thanks to the profession for their readiness always to open the stores of knowledge accumulated by their daily experience, for the benefit of persons who, like himself, had little time to make experiments or mature improvements. He had also great pleasure in bearing testimony to the excellent feeling that animated the professional brethren. They met in the Society, read papers, and compared experiences, and with an utter absence of trade rivalry and jealousy, seemed animated only with the feeling to improve each other and advance the art.

After some more music, the Chairman invited the company to leave their seats and examine the pictures exhibited. He also desired them to descend in small parties to the hall below, where Dr. Taylor's Photographie Diorama was fitted up. This exhibition, invented by Dr. Taylor, late Professor at the Andersonian University, has already been described in the PHOTOGRAPHIC NEWS, Vol. VI. p. 603, and *passim*.

Among the views exhibited was one that created a great sensation, "The Governor's House, Calcutta," as seen with the crowds of natives in front, on the occasion of reading the Peace Proclamation. The picture is first seen in sunlight, then illuminated at night with the coloured lamps on the scaffolding in front of the house, then the display of fireworks and rockets produced a most marvellous effect. A view of Bowling Bay, with the shipping, was very pretty, especially when seen under a variety of atmospheric effects; but perhaps the most remarkable was a view of Holywood, first seen in broad sunshine, then twilight, then moonlight, and finally a torch-light procession of priests in full canonicals, bearing the Host, completes the illusive and romantic scene. The exhibition of the Diorama was superintended by the Doctor himself, to whom the thanks of the Association is due for this interesting portion of the evening's entertainment. He was ably assisted by Messrs. Macnab and Bowman.

After the interval allotted to the examination of the pictures, &c., the company re-assembled, and after being regaled with a service of fruit, the music playing the while, their attention was called to an exhibition of the electric light by Mr. J. W. Stone, preceded by a brief lecture by Professor Wallace, descriptive of the peculiarities of the light. After a few illustrations of its intense power, with and without the reflector, the most interesting photographic feature of the evening occurred, the attempt in the presence of the audience to take a photograph by the electric light. The necessary apparatus being all at hand and a plate prepared by Mr. Maetear, the electric light, by the aid of the reflector, was thrown on a wall covered with photographic pictures. Great doubt was expressed whether the light was intense enough to produce a negative in any reasonable time; twenty seconds' exposure was tried, and in a very few minutes the word was passed to the Chair that the picture was perfectly successful. It was then proposed to try a more interesting object, a portrait. Another plate being prepared, Mr. Jabez Hughes was requested to sit quite steady, and with the audience on-looking, the portrait was duly attempted. Some thirty or forty seconds were given, and after a few minutes the gratifying intelligence came that the portrait was all right, but rather over-exposed. The dripping negative was speedily passed from hand to hand and declared to be a great success.

The CHAIRMAN then called on Mr. Hughes as a gentleman formerly known as a successful practitioner amongst them, but now present as a guest for a few words.

Mr. JABEZ HUGHES responded with a short enthusiastic address, comparing photography in Glasgow to what it was when he first came among them, when there was only one besides himself practising professionally. He also complimented the Association on the high position they held among photographic societies, and their great success was the more gratifying to him as he was one of the founders of the first Glasgow Photographic Society, and had had the honour of contributing the first paper ever read to them.

Mr. MACTEAR delivered a humorous and amusing narrative of the many comic mishaps to which newly-fledged photographers are subject, which excited great amusement and laughter.

An exhibition of photographs in the magic lantern followed, the slides being principally England's beautiful views in Paris, Canada, the United States, and particularly Niagara Falls.

During the interval that had elapsed from taking the electric light negatives, some of the friends had copied them as transparencies, and these were exhibited in the lantern and formed an important finale to the exhibition. The unexpected appearance of these pictures on the screen caused the greatest delight, especially the portrait of Mr. Jabez Hughes, which called forth rounds of applause.

It will be seen that the programme for the evening was of an exceedingly varied and pleasing character, and the entertainment from first to last gave universal satisfaction.

Thus closed the most brilliant and successful meeting ever held among the photographers of the West of Scotland, and the greatest credit and honour is due to the Glasgow Photographic Association for providing so interesting a meeting and setting such an excellent example to other photographic societies.

THE APPLICATION OF PHOTOGRAPHY TO THE MAGIC LANTERN EDUCATIONALLY CONSIDERED.

BY SAMUEL HIGHLEY, F.G.S., &c.*

As I have been requested to give the same subject before the Society of Arts, I shall this evening dwell upon the artistic section of my series, concerning such subjects as Kaulbach's "Reynard the Fox," and the pictures of Hogarth and Schnorr, more in accordance with the taste of this society—while on the 14th inst. I shall give my entire series of scientific objects, as being completely suited for the members of a society that have always been ready to promote scientific educational appliances.

SCIENTIFIC SUBJECTS.

GEOLOGICAL.—Penrhyn Slate Quarries—*Silurian Formation*. The Crater of Etna—*Volcanic*. PALEONTOLOGICAL.—Fossil Pterodactyle of the *Solenhofen Limestone*.—RESTORATIONS of Pterodactyle, by Waterhouse Hawkins—of the Wealden Epoch, by Professor Unger. BOTANICAL.—*Phyteleptas Macrocarpus*, or the Ivory Palm—Group of Japanese Fruit.* ZOOLOGICAL.—*Fredericella Sultana* (*Polgzoa*)—*Sepia Officianalis*, or Cuttle Fish (*Cephalopoda*)—*Rhizostoma Cuvieri*, or Jelly Fish (*Hydrozoa*). ASTRONOMICAL.—The Moon at full. ETHNOLOGICAL.—A Japanese Family.* OSTEOLOGICAL.—Skull of European. MICROSCOPICAL.—*Pinnularia* (*Diatomacea*)—Flea of the Hedgehog—Parasite of the Flea of the Hedgehog—*Acaris* of the Hedgehog—*Acaris* of the Sparrow—Section of Tooth of *Labyrinthodon*. GEOGRAPHICAL.—Views of the Falls of Niagara (from the negatives of Mr. England). BIOGRAPHICAL.—The Princess Alexandra.

ARTISTIC SUBJECTS.

Kaulbach's Illustrations to "Reynard the Fox."

Goethe's poem of "*Reineke Fuchs*" was thus epitomised by Mr. Highley.

View 1. King Noble the Lion summons all animals, both great and small, to his court at the Feast of Whitsuntide. 2. Reynard the Fox, conscious of evil doings, flinks it better to stay at home and enjoy his *otium cum dignitate*. 3. Sir Isegrim the Wolf, Frizepate the Poodle, Tybalt the Cat, and Fang the Panther, all bear witness against their neighbour Reynard, but Greybeard, the Badger, his nephew, and only friend at Court, swears that Reynard is leading a most irreproachable life, and that his accusers were themselves accomplices in his former misdeeds. Unfortunately, Chanticleer the Cock arrives with a fresh grievance, and the body of his favourite daughter Greyleg, who has been foully garotted unto death by Reynard. 4. The Cock depicts how Reynard, with sanctified men, gained access to the bosom of his family ere he treacherously betrayed his trust. 5. The King sends Bruin the Bear to summons Reynard to answer for this crime. 6. Reynard, however, on the way, leads Bruin into a trap by raising visions of unlimited honey in the hollow of a tree, and makes his way home, while Bruin meets with an *overpowering* reception. 7. King Noble, greatly enraged at his first ambassador's mishap, sends Tybalt to command Reynard's attendance, trusting that Wit and Wisdom might accomplish what Strength failed in. 8. Tybalt fares no better, and Greybeard undertakes to bring him before the King by force—*of persuasion*. To him Reynard makes confession, of how he led Isegrim to commit a *fovil* murder, and thus *take a false step* in life. 9. Reynard brought to trial, unable to contend against the charges brought against him by bird and beast, is condemned to death. 10. But, in his last dying speech and confession, Reynard turns the tables on his enemies, and by a story of buried treasure, of which he induces Puss, the timid hare, to swear he knows the hiding-place, manages to gull the King, and save his own neck. 11. Having thus risen in royal favour, and secured the imprisonment of his foes, he determines to make a pilgrimage to get out of harm's way, and receives an earnest exhortation from Bellyn, the Prelate Ram. 12.† Bellyn and Puss accompany him on the way, and inducing the latter to pay his wife a lying-in visit at his residence in the cave of Malepartus, he cannot resist the temptation of making a meal of his unsuspecting victim. 12. Bellyn, unaware of the fate of his companion, is induced by Reynard to take back a missive to the King, which proves to be (when the

wallet is opened) the head of poor Puss. King Noble in his wrath, sacrifices Bellyn as a peace-offering to Bruin and Isegrim, whom he releases from prison *instantly*. 13. The Court holds a festival to do homage to Bruin and Isegrim, who are reinstated in royal favour. 14. Reynard again induced by Greybeard to go to Court to clear his character, takes a tender farewell of his family. 15. Dame Ruckeuaw, the She Ape, and favourite monthly nurse in the King's family, pleads Reynard's cause. 16. Reynard applies the fable of the Ass, the Man, and the Spaniel to his own case. 17. And reminds the King of how his father, who was in the medical profession, through his skill, saved the life of the King's sire. 18. And relates how his arch enemy, Isegrim, got himself into trouble, in the baboon's den, by using uncourtous language to her and her family. 19. Isegrim having challenged Reynard to mortal combat, Reynard prepares himself, both inwardly and outwardly, for the encounter, under the guidance of Dame Ruckeuaw. 20. In the contest (by means of his tail, moistened and dragged on the ground), throws dust in the eyes of his enemy, till having blinded him, he falls upon him tooth and nail, and thus gains the victory over Isegrim. 21. *Being* victorious, all the beasts, *of course*, hail Reynard as conqueror: some Ass recites an ode: lauding his mental, moral, and bodily excellencies; and even the ladies look upon him with eyes of favour. 22. King Noble confers upon him the highest dignities of the animal kingdom. 23. During which time Isegrim, surrounded by his family and friends, suffers mortal agony. 24. Reynard, overpowered with honours, retires into the joys of domestic life.

"The Life of Christ," from Schnorr's "Bible Pictures," Hogarth's "Good and Idle Apprentices," and Hogarth's "Finis," concluded the series.

Beyond the department I have specially dwelt upon this evening, I may say a few words upon the Educational value of Stereographs, but only a few words, for every one must have felt their value, but, unfortunately, they have never been published in a systematic form, so as to give them a true value for the purposes of scientific instruction, but if systematically produced, the Schoolmaster, the Provincial Lecturer, and the Professor of Natural History, might bring many unique specimens, scattered through the museums of the world, within the ken of their pupils; in fact, the treasures of our British Museum might be carried in a professor's coat pocket. Such productions ought to be accompanied by descriptive letter-press, and this leads me to the application of photography to book illustration.

I was one of the first—I believe *the* first—who applied photography in this direction, for, in 1852, I illustrated a paper in the "Quarterly Journal of Microscopical Science," of which periodical I was the projector, and (at that time) proprietor, with an 8vo page plate, containing two enlarged photographs of microscopical objects, with the "imprints" exactly in counterpart of a lithographic, steel, or copper-plate print.

These two subjects were printed at one operation, on a single 8vo page of albumenized paper, in such a manner as to avoid the consumption of time and expense over the usual process of "mounting," a matter of great importance when a thousand copies had to be in the binder's hands on a given day. I subsequently published a second book illustrated with photographic plates, viz., an English edition of Dr. Unger's beautiful work on the restoration of the fossil Flora and Fauna of the different geological epochs, bearing the title, "Ideal Views of the Primitive World."

Having had some experience in this direction, I feel bound to state that we can never look to the present method of producing photographic prints, if we wish to apply the art to the purposes of book-illustration, for the cost of each print is too great for popular educational adaptation; but there is a method to which I look with hope, viz., the photo-galvanographic process of Mr. Paul Pretsch. By this invention, the counterpart of wood blocks can be produced from a photographic negative; and every publisher will, I think, back my assertion that this is the right and principal direction in which experimentalists should work; and I trust to see the day when Mr. Paul Pretsch's unwearied labours will be, as they deserve to be, crowned with complete success. For every bee in the great hive of science should sympathise with the labours of his fellow bee, while deploring that the awards and honours of the land fall too often to the share of the drones. In conclusion, I would say that every exploring expedition should be accompanied by its official photographer; that every national museum, observatory, and hospital should have its appointed operator; and

* Continued from p. 93.

† From the negatives of Messrs. Negretti and Zambra.

then the hoped-for time may come, when we can, in a systematic manner, place the records of scientific travel, the transcripts of Nature's treasures, and the history of the progress of fell disease, upon the screens of our lecture theatres, the stereographs of our cabinets, and the pages of the books in our libraries.

(To be continued.)

Proceedings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

The usual monthly meeting of the society was held in Myddelton Hall, on the evening of Thursday, February 18th; Mr. G. DAWSON in the chair.

The minutes of a previous meeting having been read and confirmed, the following gentlemen were elected members of the society:—Messrs. Parsons, Smith, James Howe, and T. Heritage.

Some specimens of the alleged spirit photographs were examined, and briefly discussed, the general impression being one of amusement at the clumsy imposture.

Mr. HILL called the attention of members, to the advantages of focussing with plain glass instead of ground glass, a much sharper image being obtained.

Mr. WHARTON SIMPSON said the method had often been recommended; Professor Emerson had especially called repeated attention to the advantages of the method. It was necessary to use a focussing glass, focussed upon the surface of the glass by means of a scratch. The naked eye might easily be deceived by seeing the image through the clear, at a little distance from it.

Mr. MARTIN said, that Messrs. Horne and Thornthwaite had long been in the habit of having a portion of the ground glass quite clear, so as to get the most delicate portion of the image quite sharp, magnifying it with an inverting eye-piece.

A desultory conversation on the subject followed, in which Mr. Simpson said an excited collodion plate was an excellent substitute for ground-glass, when that got accidentally broken. The Chairman remarked that nothing could be better, and it had the advantage of being always at hand.

Mr. SQUIRE exhibited several fine pictures taken with Shepherd's leuses, also some examples of metal printing frames, with facilities for printing several card pictures in one frame; and a Collman Sellers rolling press.

Mr. SHADBOLT exhibited a number of card portraits, some of which were by an amateur, some by Mr. Robison, some by Mr. Bannister, and others by Mr. Wenderoth, of Philadelphia. He was induced to bring the latter pictures before the meeting again, because he feared the last time they were examined they scarcely received justice from being shown in the rough, unmounted.

Mr. SIMPSON remarked, that at their best estate they were not very good; they were very hard, and devoid of half tone. They were not a fair sample of American photography, which was usually very good.

The CHAIRMAN said they were certainly hard and poor, not equal to some of the amateur pictures then before them.

The specimens by Mr. Bannister were produced, it was explained, from negatives on curved glass.

Mr. HILL said that probably accounted for the distortion observable in the background objects.

Mr. SHADBOLT said he thought the curve was so slight, only one-tenth of an inch rise in the middle of the plate, that it would not produce any perceptible change in the lines. He thought Mr. Hill was deceived by the ugly ill-drawn background. Anything more hideous he had never seen.

The CHAIRMAN said with respect to the curvature of the glass, twelve months ago Mr. Ross had tried hard to induce photographers to use such plates, but he (the Chairman) had always felt that they would not willingly use anything which involved much extra trouble. It was certainly a pity that since the distortion and astigmatism introduced by the endeavour to produce flat fields could be got rid of by using a curved glass, that photographers would not do it.

After some further conversation, and some routine business in nomination of officers to be elected next month,

Mr. REJLANDER, having apologized for not being prepared with a proper paper, read some desultory observations on "Art-Photography," illustrating his remarks by some very fine photographic art studies, which were examined with much interest, after which the proceedings terminated.

The International Exhibition.

REPORT OF THE JURY ON PHOTOGRAPHY AND PHOTOGRAPHIC APPARATUS.*

In proceeding to some brief considerations of those contributions in Class XIV., which possess especial interest, the Jury feel it important to state that the limits of this Report preclude the possibility of any extended notice of even the most meritorious works, and to add, that silence in reference to any contribution must not be understood as necessarily implying any want of merit in the work, or of interest on the part of the Jurors, their object in the following comments being chiefly to direct attention to such contributions as, apart from their individual merit, are possessed of features interesting to the public, or to those interested in the art, either professionally or as amateurs.

APPARATUS, &c.

To commence with the means, before entering on results, we shall refer to the apparatus first, and here it is necessary to say, that the high excellence of the photographic appliances in the British department was worthy of every commendation.

The uniformity of this excellence was such as to present some embarrassment to the Jury, and they felt it impossible to make a distinction by awarding a medal to any, whilst every contribution was worthy of honourable mention. They have pleasure here, therefore, in recording the fact, that it was rather from equality of excellence, than from inferiority in any respect, that medals were not awarded to apparatus in the British department of Class XIV.

UNITED KINGDOM.

3033 AUSTEN, W. (H. M.)—This contributor is the inventor and manufacturer of improved rolling machines for closing the fibre of the paper upon which the photograph is printed, and giving it an ivory-like appearance; also of camera-stands made of iron with universal motions, together with various iron head-rests. The advantages claimed for iron over wood consist in its freedom from warping or shrinking in changes of temperature, and in securing rigidity and firmness without cumbersome bulk. The rolling presses exhibited appear to be singularly well made and efficient. The bed, instead of consisting, as is usual, of a plate of steel fastened on wood, is of one solid piece of cast steel. The head-rests are provided with ball-and-socket joints, which afford great facility of adjustment. One of the rests for standing figures is provided with a support for the back as well as the head, which materially contributes to comfort and firmness whilst standing for a portrait. The contributor deserves commendation alike for the ingenuity of his applications, and the excellence of workmanship in his apparatus.

3043 BLAND and Co. (H. M.)—This firm exhibit a variety of cameras, baths, shutters, vessels, &c., which are made with an especial view to the changes of temperature and other trying conditions found in India and other tropical climates. Not simply in the designs and in the perfect seasoning of the raw materials is this purpose remembered, but in the mode of workmanship, &c., glue not being relied upon for the adhesion of the parts, an excellent universal camera is shown which may be used for stereoscopic pictures, or album portraits; it may be employed in the field as well as in the glass room, being equipped with a series of frames for dry plates, as well as with the usual appliances for wet processes. The camera is provided with an arrangement for sliding the lenses inside, for the convenience of packing; a convenient and portable chemical chest accompanies the camera. The water-tight bath exhibited has the cover conveniently attached, which prevents the chances of mislaying; at the bottom of the mahogany outer case is an opening which permits the contents of the glass bath to be examined. An ingenious instantaneous shutter, closing with a spring, is also exhibited; and a variety of other cameras, &c., combining many improvements with good quality and handsome design.

MESSRS. BLANN and Co., as wholesale agents, exhibit the only collodion to which a Medal was awarded, that of Mr. PONTING of Bristol (3136). This collodion, on trial by the Jury, fully bore out the reputation it has obtained amongst practical photographers as extremely rapid, and giving very perfect delicate negatives, full of half tone and brilliancy. The stability of this collodion is a feature to which the Jurors call especial attention. At the period when the trial was made, the sensitive collodion had been prepared some months; and as some of the members had been in the habit of using the same preparation, they were enabled, by their individual experience, to confirm and endorse the results of the trial then made as to the high character for sensitiveness and stability of this collodion.

3047 BOUQUIN and Co. (H. M.)—A variety of cameras and camera-stands, albums, &c., are exhibited by this firm. The camera-stands are good in design and workmanship. A large camera, combining a multiplicity of objects, being suited for copying and enlargements as well as for ordinary purposes, and extending from four and a half to forty inches, possesses many excellent qualities. The albums by this firm are superior in design material, and manufacture, the tint of the paper giving the best effect to the photographs mounted therein.

3053 BELL, J. T. and G. (H. M.)—A variety of pictorial backgrounds and profiles; accessories chiefly intended for use in the production of carte de visite portraits; they demand attention from the variety of the designs and from the novel application of the art of the scene-painter as an auxiliary to that of the photographer.

3064 COX, F. J. (H. M.) contributes a variety of excellent apparatus, amongst which may be named an instantaneous shutter, which is placed between the anterior and posterior lenses of a portrait combination in contact with the central diaphragm; a dark slide or "camera shield" which revolves and exposes alternately different parts of one large plate, and permits several different pictures to be taken on the same glass; a plate containing seventeen different portraits being exhibited as an illustration; these portraits are glass positives of great brilliancy, and are stated to have been produced by

* Continued from p. 58.

Fisher's positive collodion, and developed with a solution of proto-nitrate of iron with formic acid.

3069 DALLMEYER, J. H. (Medal).—The contributions of this exhibitor consist of a variety of photographic lenses and apparatus.

The lenses for the great excellence in which the Medal was awarded, consisted chiefly of double and triple achromatic combinations possessing novel features of great importance. The triple achromatic lens invented by Mr. Dallmeyer consists of three achromatic lenses, the front and back of which are positive, the central one being negative. In each of these combinations the combined surfaces are cemented, thus giving the same number of reflecting surfaces as the ordinary portrait lens. The negative central lens is of the exact form and power required to correct the central and eccentric pencils, and this with full aperture. The triple lens is free from chromatic and spherical aberrations. The images produced by this lens are quite free from distortion; a wide angle of view, with good definition, is included by it. For copying and architectural purposes it is especially valuable, giving perfectly straight lines, a flat field, and great equality of illumination and definition. In the hands of the Jurors these qualities have been satisfactorily proved, and in the beautiful landscapes produced by this lens, and exhibited in the building, additional confirmation is obtained.

Several quick-acting lenses, with flat field and fine definition, especially adapted for card portraits and other larger pictures have been invented by Mr. Dallmeyer. A double combination, especially designed for instantaneous stereoscopic views, and also a lens adapted for enlargements, specimens of which are exhibited by Mr. T. K. Williams (3182).

The medal has been awarded for the introduction of novelties as well as for unsurpassed excellence of manufacture.

Some excellent samples of apparatus, consisting of cameras, instantaneous shutters, are also exhibited. A camera for carrying two stereoscopic lenses possesses a moveable front and diaphragm, which permits it also to be used with one lens for producing landscapes $7\frac{1}{2}$ by 4 $\frac{1}{2}$. The use of the double rack and pinion for adjusting the focus by sliding the front body of the camera is worthy of notice.

3071 DAVIS, T. S. (H. M.), contributes a photographic manipulating camera. It consists of a small chamber, with drapery to surround the operator, forming a dark tent; the chamber is fitted with bath, dishes, and other requisites; the lenses are attached to the front of the chamber, and the focusing screen is fixed inside, the plate being withdrawn from the bath *in situ*, and exposed and developed without the operator leaving his position in the dark tent formed by the drapery attached to the chamber. This contrivance is in some respects similar to Arber's camera, and is very compact and convenient for operating in the field.

3080 HAAR, G. (H. M.). Cameras of very excellent quality, well seasoned and well made; a portable stereoscopic camera and improved Kinneer's camera were both worthy of attention. Mr. Haare manufactures largely for the wholesale trade.

3095 HIGLEY, S. (H. M.).—A variety of contributions are shown by this exhibitor, who received an award for the general excellence of his apparatus, consisting of a photo-micrographic camera for taking enlarged photographs of microscopic objects; a photographer's actinometer, by which the time of exposure required in a given light of any class of objects, may be tested; a new form of dropping bottle for nitrate of silver; solutions, acids, &c.; an improved pneumatic holder; a photographer's travelling lamp to be used when developing, and a portable tripod developing stand. Much ingenuity of contrivance is displayed in all these articles.

3097 HOCKIN and WILSON (H. M.).—Apparatus and chemicals of great excellence are displayed by this firm, amongst which may be named an instantaneous shutter made of brass, closing with a spring; vessels of ebonite for photographic purposes; hermetically sealed tubes, or bottles for collodion, ether, and various other chemicals.

The chemicals are of great purity; the collodion, a preparation of which Mr. Hockin was one of the earliest manufacturers, is possessed of great intensity, and for many purposes is highly valuable. They also exhibit a portable tent intended for field operations.

3099 HOCKIN and WILLIAMS (H. M.).—The contributions of this firm consist of a variety of photographic chemicals of great purity, and of which they are the manufacturers on a large scale for supplying retail dealers. The samples exhibited fully sustain the long-established reputation of this house for the care used in securing purity in their productions.

(To be continued.)

Photographic Notes and Queries.

CONTINUED USE OF THE SAME TONING BATH.

DEAR SIR,—For some time past I have meditated laying before you one of my experiences on the much vexed question of Alkaline Gold Toning, and some remarks in the paper of your able correspondents. "A Photographic Assistant," on the subject of old gold baths, makes me think this the fitting opportunity to do so.

In lieu of making a fresh bath for each batch of prints, I have for some months past been in the habit of continuing to use an old one over and over again with a result fully satisfactory to myself both as to the tone arrived at and the economy of the gold, having always been able to reach it with purple tint approaching to black without the smallest tendency to that dreaded arch-enemy mealiness. I have invariably found on first using a new bath that the prints, though of satisfactory tint on leaving it, receded to a sepia tint in the hyposulphate of soda; but this never occurs on the second using, and it is a great convenience, as an amateur, to be able to work off one or two prints at a time by having a bath constantly ready.

The course I pursue is to make the bath with distilled water, and having inserted in it a small piece of litmus paper, add in small portions at a time bicarbonate of soda until the blue

colour is all but restored; then, from time to time, if the bath becomes inert, I add from 6 to 8 drops of a 4-grain gold solution (or more if so large a number of prints have been through as to nearly exhaust it), which at once sets up the action, and in extreme cold I have sometimes warmed slightly to save time, I do not find that it requires further alkalizing, or that I get any large precipitate of gold thrown down. I may add that I usually print on the albumenized paper of the London Stereoscopic Company, floating two minutes in a bath made at 100 grains to the ounce, and never allowed to fall below 90 grains, and thoroughly washed before toning.

In all this I may be telling you nothing new; and, if so, have to crave your pardon for troubling you; but I have never met with it in print or practice; and if you think it likely to be useful to others, I shall be much gratified in having contributed my mite to the general stock.—I am, yours obediently,

F. LANE.

P.S.—I enclose a small print as a specimen of tone.

Rotherham, Feb. 6, 1863.

[The print enclosed is an architectural subject; the tone a good purple black.—ED.]

MORPHINE DRY PROCESS.

DEAR SIR,—In reply to your correspondent's inquiries, ho must obtain the *miriate*, not *acetate*, of morphine, dissolve it in a little water, add it to the bath, and filter out the chloride or muriate of silver, when the *nitrate* of morphine remains in solution, which salt is, I believe, not manufactured for sale. As to the exposure required in this process, all I can say is that the plates are very sensitive, may be requiring half as long again as a wet plate. I generally varnish round the edge of the plate before development, and do not use any coating above or underneath the collodion. I have only worked stereoscopic plates, on account of the increased expense of large ones, but I see no reason why an edging of varnish should not do for them also, especially with a non-contractile collodion; there is no wrinkling and loosening of the film, as in the tannin process. It is important not to use water containing lime, or much inorganic matter in solution; filtered fresh fallen rain water is good; after excitation immerse in a vertical bath of this water, giving an up and down motion to the plate for fifteen seconds or so; then, after an interval of a minute or two, immerse in another lot of water, and so on, to get rid of all the nitrate. For development, I far prefer iron to any other agent, and from my experience with it on these plates, it appears to act thus: if under-exposed, the picture lacks detail and intensity, after one application of developer; another will increase the detail, and, if necessary, a third dose or fourth will augment the half tones, and not much increase the density, which must then be gained by the use of pyro and silver. If, on the contrary, the plate has been fully exposed, the iron developer will bring up the whole of the detail on the first application, and a second will increase the density very much. I have taken many stereo negatives, which were completed with two doses of iron, and a few drops of silver solution added on using. In making a new bath, I expose it to the light for a week or so, which facilitates the deposition of a black powder, which is then filtered out, and the solution will keep much longer in a clear state afterwards, although it is always good for use if filtered.—I am, dear sir, yours respectfully,

WM. BARTHOLOMEW.

Farnham, Surrey, Feb. 22, 1863.

PHOTOGRAPHIC HALF-HOLIDAY.

DEAR SIR,—Will you kindly insert in your next Friday's NEWS, that an attempt is now being made to afford all those who are engaged in photography the benefit of the Saturday half-holiday, by soliciting the various photographers in the city to close their respective establishments at two o'clock on Saturday afternoons throughout the year, commencing March 7th (the day on which the Princess Alexandra passes through the city.)

The time of closing (two o'clock), has been chosen, as in many houses it would be impossible for business to be concluded, and negatives varnished, &c., before three o'clock, so that the latter may be calculated as the hour of leaving.

I trust that all who are concerned in photography will give this movement their warmest support.—I remain, dear sir, yours truly,

H. J. GOLDBOLD.

[We very heartily commend this suggestion to employers,

and may add our conviction, that in granting the boon, it will not be all loss to them, as their operators will doubtless work with renewed zest and energy in consideration of such a privilege. It would, moreover, afford to some the opportunity for occasionally trying a landscape, an opportunity for which those constantly immured in the operating room often sigh and hope at present in vain.—Ed.]

ENLARGING WITH A STANHOPE LENS.

DEAR SIR,—I think your correspondent, Mr. Leary would find that in using the Stanhope lens for taking photographs of microscopic objects, the double combination of lenses has the effect of neutralizing to a considerable extent the coloured fringe which surrounds the object when seen with the Stanhope lens only. The use of the Stanhope lens was only advocated by me as a *cheap* means of taking these photographs, or studying the structure of insects and plants. If only the latter object is desired, we have a very cheap contrivance with the Stanhope lens, costing 2s. 6d., and a long deal box, with the bottom made to slide (in the centre of which the Stanhope lens is fixed), and the top fitted with a piece of ground glass, which box any carpenter would make of deal, for a trifle.

I think, for enlarging from small negatives, a large double-bodied camera of deal, painted black, is certainly the cheapest, and perhaps the best apparatus for the purpose; indeed, I cannot say that I see any great improvement upon the method of enlargement, which I have used for years, and a description of which will be found in the first volume of the NEWS. I think we shall never get a really satisfactory enlargement of a portrait until we get a film on the glass that will bear magnifying to the required size without showing the structure; all the enlarged photographs that I have seen look as if the sifter were pifted with the small-pox, which does not improve the appearance.

I have noticed some remarks in recent numbers of the NEWS, on the use of "Ammonia nitrate of silver in alcohol," for albumenized paper. I have found the formula, mentioned in vol. i. page 141, to answer well with some albumenized paper, but in many cases, it has dissolved the albumen; perhaps floating for a very short time would succeed, as the solution penetrates the paper almost immediately, or using more silver, only, in that case, I think the paper must be used immediately after sensitizing, as even with ten grains to the ounce it soon begins to change.—Believe me, my dear sir, yours very truly,

THOMAS BARRETT.

Miscellaneous.

PHOTOGRAPHS IN PRINTING INK.—A correspondence has recently taken place in the *Times*, which illustrates how amusingly uninformed even the intelligent portions of the outside world remain as to progress and capabilities of photography. First a paragraph appeared announcing an "Important Discovery in Photography." This, however, merely turned out to be Mr. Pouncey's process, the alleged discovery being the production of photographs in printing ink, and was stated as follows:—"This ink is mixed with certain chemicals, and spread completely over the paper intended to be submitted to the action of the rays of light through a negative; and the secret consists in rendering it so sensitive that an indelible photograph may be fixed on the paper, leaving the other portions so free as to be easily washed off. The time required for exposure is comparatively short, and the advantage is, besides that of permanence, the fact of the subject being fixed, developed, and, as it were, completed without the various manipulations required under the old system. The superfluous ink is removed by spirits in ten minutes or a quarter of an hour, displaying a picture for delicacy of tone, beautiful gradation of light and shade, and minuteness of detail fully equal to anything heretofore obtained in photographic printing." A letter from Mr. Osborne followed, correcting the erroneous notion that the application of printing ink was a new discovery, and briefly detailing the history of its application, first, in 1859, by M. Asser; next by himself, and subsequently by Col. James: all of whom not only produced photographs in printing ink, but also transferred them to stone for reproduction by a printing press. He adds:—"That Mr. Pouncey may have a special method of his own I do not doubt, nor do I wish to take from him any of the merit to which he is entitled; but to the statement that the results he has obtained are perfect,

or excellent, I must demur, if we are to judge by the specimens exhibited by him at a recent meeting of the Photographic Society, and by the manner in which they were received by the members present." Mr. Paul Pretsch next writes claiming the invention as early as 1854. There is just this distinction to be made, however, between the latter gentleman's ingenious methods and those before referred to:—The former refer to producing from a negative an image on paper in printing ink; the latter to the production, by the aid of a negative, of a plate or block from which to print in the ordinary way. In fact, Mr. Pretsch incidentally indicates the difference in his communication: he claims, simply, reproducing photographs in printing ink; the other claims are for producing them direct from the negative.

STEREOGRAPHS OF THE MOON.—A singular question as to certain photographs of the moon recently published in a work entitled "Our Satellite," by Dr. Le Vengeur d'Orsan, has been raised by the *Athenaeum*, in which a possible case of disgraceful piracy is involved. The *Athenaeum*, in a recent number, says:—"Looking at one of Mr. De la Rue's photographs of the moon, we were struck with its minute resemblance to one recently published by Dr. D'Orsan—even to the appearance of a casual flaw in the glass. Whereupon we asked the question—When was Dr. D'Orsan's negative taken? In reply we have a letter from J. B. Morgan, the Doctor's Secretary, from which we quote this passage:—"Dr. D'Orsan always treated such covertly scurrilous personal attacks with dignified indifference, and would also meet those recently made with contempt, did not the interests of his publisher render the publication of an authorised contradiction of the recent mis-statements a matter of necessity." Unhappily, the Doctor's Secretary forgets to answer the question put. As we are not told when Dr. D'Orsan's negative was taken, we are unable to say which of the two lunar photographs before us was the original." In a subsequent number, a letter from Messrs. Smith and Beek appears, in which they distinctly charge Dr. D'Orsan with piracy from a stereoscopic transparency by Mr. De la Rue, published by them. "The proofs of this statement," they say, "are as follows:—Not only are the photographs exactly similar as regards both lunation and libration, but the very flaws in the collodion film of the original negative are reproduced in Dr. D'Orsan's prints. One of the most prominent of these flaws is situated in a small plane to the N.W. of Tycho, between Orontius and Sasserides. It appears as a white speck on the collodion film of the original negative, and is reproduced as a black marking in the positive print published in the stereoscopic slide. It is reproduced again in both photographs of Dr. D'Orsan; thus proving, not only the source from which he has obtained the photographs, but that both his published photographs, although professing to be taken at different lunations, are from one and the same photograph. In one of them the outlying parts around Tycho have been carefully expunged. There are at least half-a-dozen flaws reproduced, but the above-mentioned is, we think, sufficient." In reply to this, Mr. Bennett, the publisher of Dr. D'Orsan's work, states that this gentleman is willing to show to any scientific gentleman, his original negatives, and the date of their reproduction, proving their priority to those of Mr. De la Rue. He adds, that "to distinguish between minute flaws in the negative, and hitherto undiscovered 'flaws,' so to speak, on the surface of the moon, would require a most accurate and critical series of observations." For the present, the matter remains there. The quarrel is a very pretty one as it stands. Since the above was in type, Mr. De la Rue has written a voluminous letter with illustrations, to the *Athenaeum*, in which he very satisfactorily shows that Dr. D'Orsan's published photographs are simply unauthorized copies of his own. Mr. Bennett, Dr. D'Orsan's publisher, has also written to state, that, having applied in vain to that gentleman for dates, and a sight of his negatives, he has come to the conclusion, that it is not in Dr. D'Orsan's power to produce evidence to overthrow the grave charges made, and that until such evidence is forthcoming, the publication of "Our Satellite," will be discontinued.

LECTURES ON PHOTOGRAPHY.—We find, from a Berkshire paper, that a lecture on photography was recently delivered at the Working Men's Institution at Newbury, by Mr. E. T. Brooks a professional photographer in that town. We think that much might be done to place correct notions of our art in the public mind, by popular lectures of this kind, and remove fallacious notions. The subject could always be made interesting.

Talk in the Studio.

PHOTOGRAPHIC EXHIBITION.—We must remind our readers that the Exhibition closes on the 2nd of March, and that it is now open in the evenings.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—We are requested to inform the members of this Society that the address of the secretary, Mr. Alfred Harman, is now, 7, Gunnersby Villas, Harter's Road, Peckham, S.E. Mr. Harman has recently dissolved all connection with his late partner, Mr. Dages, and is now engaged in business at the above address.

BULLOCK'S MOUNTING MACHINE.—This is a cleverly contrived aid to the mounting of card portraits. A raised plate, the exact size of the print, is fixed in the centre of a piece of mahogany. At each end is a hand or "gripper" resting on a spring; these hold the print in its place whilst it is pasted. The card is then laid upon it, the edge touching certain guides which give exactly the right margin on the card. The points are then slipped off the print, the card pressed down, and the operation is complete. Perhaps this seems more complicated in description than it is in fact; and we are assured that a great saving of time and increase in the neatness of the mounting is obtained by the use of this little contrivance.

SUTTON'S PATENT ALBUMENIZED PAPER.—We are informed that the manipulatory difficulties attending the production of this new paper are now nearly, if not entirely, removed, and that Messrs. Lampray, Tibbitts and Co., will be prepared shortly to supply it to the public. We have seen some proofs on this paper produced in an early stage of the experiments when the *modus operandi* was in a comparatively crude state, which were highly satisfactory. The surface of the paper being peculiarly delicate and grainless. The advantages claimed for this paper are, mainly, that it has an unusually fine surface, that it produces a better tone, and greater detail, especially in very deep shadows; that it is free from meanness, and that really bad prints are almost impossible. We understand that shortly a fine collection of prints on this patent paper, the production of different distinguished artists, will be ready for inspection at the establishment of the manufacturers. Some of the prints are on tinted paper, producing a very pleasing effect.

To Correspondents.

*** Several columns of Advertisements are compelled to stand over for want of space.

PHOTOGRAPHIC NEWS ALMANAC, AND YEAR-BOOK OF PHOTOGRAPHY.—This work is now reprinted, and is ready for issue.

PHOTO. A.—The streakiness in the direction of the dip may arise from several causes. A very common and generally efficient remedy is the addition of a little acid. It will sometimes arise from the accumulation of ether and alcohol in the bath, and in that case, removing these by evaporation is necessary. It will sometimes occur from the presence of organic matter in the bath, in that case, a simple remedy, generally efficient, is the addition of a little bicarbonate of soda, just sufficient to cause a slight precipitate, which is not redissolved on agitation. Then place the bath in the sun for an hour or two, and afterwards filter, and if necessary, acidify. A strong bath generally favours vigour, but increases the tendency to stains.

S. CHESTER.—The line to which you refer means simply what it says: "distilled water 1000 grains;" that is, 2 ounces and 40 minims of distilled water; but we phrased it in the words of M. Jeanrenaud.

R. T. W.—The specimens are very creditable for an amateur with few opportunities. You will obtain a better idea of your chances as an operator and of the remuneration, by answering some of the many advertisements for assistants which constantly appear in our columns, than we can give you. 2. Chloride of lime is often used for cleaning or removing discolouration of engravings; but we cannot tell whether it will remove the stains to which you refer.

J. R. H.—The rapid discolouration of the silver bath often proceeds from some peculiarity of the albumenized paper; but we have not met with a case which resisted attempts to clear by citric acid, kaolin, &c. We can only recommend you to make the bath neutral, or slightly alkaline, and then add solution of citric acid until a precipitate takes place; this will most likely clear it. Sunning the bath after it has been rendered alkaline, will also clear it. When using common water you should not add any acid or you may dissolve some of the insoluble salts which helped to keep the bath clear.

F. L. E.—There are several methods of photographic engraving by the aid of bitumen. You will find a summarised history of several on page 71, vol. i., of the PHOTOGRAPHIC NEWS; on page 247 of the same volume you will find particulars of the original process of M. Nicéphore Niepce; on pages 133 and 158, of our second volume, you will find a process by M. Bertchold. The most detailed account of the process of M. Nicépce de St. Victor and M. Lemaitre, that we know, is given in Monckhoven's *Traité Général de Photographie*, of which a new edition has just been published.

JUSTITIA.—A photograph published or sold before the passing of the New Copyright Act is not protected, and you have no remedy against the piracy. 2. The defect in the pictures received is *meanness*. Many remedies have appeared

in our pages, many of which are at times useful; but sometimes the defect seems to defy all remedy. Read the various articles we have published on the subject. The defect is much more common with thin than with vigorous negatives. There are no especial instructions to be observed in making the acetate bath, beyond following the formula, and keeping the solution a few days before using it. 3. You have light too evenly all round the sitter; more side light and less front light is desirable, this will give more vigour and roundness to your figures.

J. BURGESS.—Your letter did not contain the sample of paper alluded to. Albumenized paper prepared with fresh eggs, and 24 grains of chloride of ammonium will doubtless make a good paper, but will require a very strong silver bath. We should prefer half the quantity of chloride.

M. A.—Ammonia-nitrate, when successfully worked, gives very rich deep tones; but there is no fault to be found with the tones of the cards enclosed. 2. A newly iodized collodion, especially if it contain cadmium, generally has a tendency to give veiled negatives. It sometimes happens that the veil does interfere with the quality of the print, if the relations between lights and shadows are properly preserved; but it retards the printing very much. 3. As a general principle a bath for landscape purposes will bear more acid than one for portrait negatives. If your tannin plates have a tendency to fog, the bath should have more acid. 4. The PHOTOGRAPHIC YEAR-BOOK is reprinted. The Photographic Exhibition closes on the second of March.

A CONSTANT READER.—If albumenized paper be quite dry when placed in the printing-frame, it ought not to cockle. It is probable that the back of the frame is damp in such case. 2. A piece of felt is a good thing to place upon the print in the frame. 3. When the free nitrate solution collects on the plate in streams during exposure, it indicates that the plate had not been sufficiently long in the bath; that the collodion is of a very repellent character, and may be remedied by the addition of a drop or two of distilled water, or that the bath is very old. We do not like redipping in the bath as it often causes fog. 4. The imperfect surface to which you refer is too generally described to enable us to help you. If we saw a specimen we could perhaps give some advice. 5. The cause of varnish cracking has been the subject of much discussion; it is generally believed that damp is the primary cause. 6. We prefer the lenses of the best English makers to any French ones.

R. G.—It entirely depends on the size of a dish, whether one made entirely of gutta-percha, or one of wood lined with gutta-percha, will be cheaper. If very large, the latter will probably cost less and be more useful. 2. To precipitate silver from hypo solutions, use liver of sulphur.

NO NAME.—We received an envelope from some of our correspondents, posted in the West Central district, in which the letter had been omitted. The envelope was unsealed as well as empty, with a note on it from the local postmaster saying it was received so. This being the case, we do not know whether the letter had never been put in, or lost out, only that we have nothing to answer.

An article on "Glass Rooms," with a Diagram of Mr. Rejlander's studio, together with several other articles and "Critical Notices" are compelled to stand over for want of space.

Several Correspondents in our next.

GLASS HOUSES AND LIGHTING.

From the frequent inquiries which reach us, asking for advice and information relative to the building of the glass-house, and lighting of the figure, we are led to believe that few subjects are more interesting, or less understood, amongst photographers. Whilst it is difficult either to deal with such a question in the abstract, or prescribe rules of universal application, we can occasionally give illustrations of specific cases, and suggest general principles.

We do not know of any photographer who has produced more artistic pictures than Mr. Rejlander. One of the first reflections which strike us, on looking over a collection of these photographs, is the unusual command over the lighting of the model which the artist possesses: almost every variety of lighting is adopted in turn, to serve some specific purpose, and always successfully. To the education of an artist, Mr. Rejlander has added years of practice as a photographer, not simply in manufacturing conventional portraits, but in producing art studies, in which every possible effect of lighting is in turn necessary. Mr. Rejlander has recently erected a new studio in London, a brief description of which cannot fail to be interesting to our readers, not necessarily as a model to be imitated, but as illustrating the principles of lighting, which may be adopted or modified as circumstances may render necessary. We should state at the outset that the chief aim in the present studio is to secure a mode of lighting similar to that used by painters, so that the photographic studies obtained may be strictly available for painters, the same conditions of light and shadow existing in the photograph, which are required in the painting. That the same light will often be valuable for portraiture, and general photography, we see no reason to doubt; the only misgiving we have on the subject, being in relation to the amount of light, which we fear would scarcely be found sufficient for convenient working in dull weather. Here is a sketch of the erection.

It is built of corrugated iron; and the total length is thirty feet. The portion devoted to the sitter is ten feet long and eleven feet wide. The remaining twenty feet curving in near the door, and becoming narrower, so that, at the extreme end, where the dark room is, the width is seven feet. The light is obtained solely from the white spaces *a, b, c, d, e, f*, in the diagram, the light falling from

the north-west. The door *a* consists of a plate of glass, seven feet high by three feet wide. The window adjoining, *b*, consists of another plate of glass, seven feet high by five feet wide; this joins another plate, *c*, in the roof, which is five feet wide and three feet deep. These three are of white plate glass, and constitute the chief source of light. On the opposite side there is no glass at all, but the interior is painted white to secure reflected lights. The minor lights, *d, e*, and *f*, will generally be covered with blinds, their object being to secure not direct light, but diffused light, and thus aid the reflections.

It will be seen that the sitter is lighted from the side and side top: front light, and direct vertical light being entirely avoided. The absence of sash bars is in Mr. Rejlander's opinion a great advantage to the sitter and to the picture. The effect of these bars on the eye having a painful sensation, interfering with natural expression, and spoiling the beauty of the eye in the picture. The camera is in comparative darkness, enabling the operator to focus without the aid of a dark cloth over his head. The eye of the model also looks into this darkness, by which is gained the double advantage of comfort to the sitter and expansion of the pupil of the eye, giving it more depth and expression. Nothing is more offensive in a photographic portrait than the light unmeaning-looking eye, which often results from the sitter looking towards the light, in which case the pupil contracts; and, if the irides be blue or grey, giving at once a weak, fishy, washed-out effect to eyes, which, in the original, probably look dark and bright, and beaming with expression.

We may here subjoin a diagram, showing the longitudinal section of a glass room proposed some time ago by Mr. Sutton, to which Mr. Rejlander's is very similar in principle.

The total length here is supposed to be thirty-six feet, of which twelve feet, *A, B, C*, constitute the glass room proper. *A, B*, on each side, is opaque, and *B, C*, on each side, glass, from top to bottom. This, with the small portion, *c* to *d*, at the front of the glass room, and adjoining the narrow passage, is all the glass the building will contain, the remainder being a long, dark passage, as in

Mr. Rejlander's studio. The end, A, at which the background will be placed, must be south, so that the light reaches the sitter from the north. The windows, facing east and west, must be furnished with blinds, one of which, according to circumstances, will always be down, just allowing sufficient light to pass through, to serve as reflected light.

The front top window, *d*, it is recommended, should be made to open and fall back upon the roof of the passage, so as to let in air and more light in fine weather. The chief objection to this also is that existing in Mr. Rejlander's room, namely, that in dull weather, and amid the smoky atmosphere of large towns, such a room would often be found to be too dark for practical purposes of portraiture, so that it is desirable to have facilities for getting in more light when necessary. In Mr. Sutton's design we conceive it would be an advantage, instead of continuing the opaque roof of the glass room over the entire space, *a, b, c*, to let it be opaque merely over *a, b*, the glass then commencing and sloping to the roof of the dark passage, forming a line from *b* to *d*. This would give more light without serious sacrifice in other respects.

In both these designs it will readily be seen that excellent principles of lighting are involved, which are well worthy of consideration. Not the least of the benefits to be secured consists in cleanness of the shadows, and consequent brilliancy without much intensifying, as there is scarcely any chance of that bane of iron development—deposit on the shadows from diffused light entering the camera. For further details on the subject of erecting glass-houses and lighting the sitter, we refer our readers to an article in the YEAR-BOOK OF PHOTOGRAPHY for 1863, which is just reprinted.

PHOTOGRAPHIC EXHIBITION.

FINAL NOTICE.

The number of reproductions in this exhibition is not large. With the exception of three or four very fine things by Mr. Annan, and a few others we have noticed before, the copies of Turner's paintings by Mr. Thurston Thompson are the only reproductions worthy of mention in the exhibition. These are, as a series, perhaps, the most perfect copies of oil paintings which have ever been produced by the aid of photography. It is a somewhat singular fact that pictures, the great charms of which consist in their gorgeous colouring and wondrous aerial perspective, rather than in sharply defined drawing, should, in the photographic monochrome, so accurately render the feeling and characteristic style of the master; yet, it is a fact, that in no copies of paintings we have before seen, is the photograph more satisfactory, or the original painting more ably translated into monochrome. Here is "Spithead" (241), which will rival any engraving possible of the same subject, as a picture, whilst, as a study of Turner, not the most admirably drawn copy by hand can compare with it. "Venice" is a picture consisting of little more than sunlight and atmosphere, which seems to robe every object in a fairy-like veil; it is one pre-eminently difficult from which to produce an effective photograph; yet in the copy before us there is the perfect suggestion of the original, which it enables us to bring most vividly before the mind's eye. "Carthage" is one of the most glorious pictures of the series, and a perfect study of atmosphere and composition. Mr. Thompson has conquered all the difficulties which might readily have been supposed insurmountable in photographing these pictures; the glowing colours, the indefinite drawing, the heavy impasting and peculiar handling, have all yielded to the skill, taste, and experience brought to bear in copying them; and it is a matter of congratulation for the public, that probably the only opportunity which will occur—the removal from one gallery to another—was seized for obtaining such invaluable transcripts. We are glad to be able to state that this series will shortly be published, and afford every

admirer of Turner, and every student of art or of photography, the facility of obtaining some of the most valuable contributions which photography has yet made to art. Mr. Thompson exhibits some other copies of pictures, and few photographs of *bas reliefs*, in terra-cotta we believe, by Clodion. There is also a copy of a marble bust by Hiram Powers, "Proserpine" (254), which is as perfect a specimen of delicacy, roundness, and satisfactory rendering of texture as we have ever seen.

The London Stereoscopic Company exhibit a fine collection of their admiral photographs of objects in the International Exhibition, which we have noticed before, and which all the world knows by this time to be almost as perfect as photographs can be.

Mr. Stephen Thompson exhibits some photographs of sculpture, amongst which we may name copies of Foley's Egeria, both the bust and complete statue, as possessing considerable force and delicacy; a little more reflected light in the deep shadows would, we think, have more accurately rendered the texture of marble.

Amongst instantaneous photographs, claiming especial pre-eminence as being unsurpassed for beauty, and unequalled for size, are the pictures of Col. Stuart Wortley, consisting chiefly of scenes in Italy, and possess, in almost every instance, clouds of most wondrous beauty, in combination with sea and foreground. The sweep and dash of the waves, the smoke of Vesuvius in the distance, mingled with the grand masses of cloud, are all very beautiful and effective. The modes of producing these pictures was recently very fully and lucidly described in our pages. A strongly bromized collodion; a nitrate bath containing a full dose of nitric acid; an iron developer with formic acid; a 6 by 5, or 8½ by 6½ triple lens with full aperture, for pictures on 10 by 8 or 12 by 10 plates; intensifying after the plates are dry with mercury and an iodide, followed by pyrogallic acid and silver. These give, in all photographic respects, such softness, detail, clearness, brilliancy, &c., as much perfection as the pictures possess in an artistic sense. Col. Stuart Wortley also exhibits a few very perfect tannin pictures, which leave nothing to be desired; one of these has also had an instantaneous, or very rapid exposure.

Mr. Blanchard's stereographs are the only other instantaneous pictures on paper exhibited. Mr. Wilson does not contribute at all this year. Mr. Blanchard's pictures consist of instantaneous views of London and the Thames; busy, bustling, street scenes; and combinations of water, shipping, and magnificent clouds. It is unnecessary to dwell further on these pictures than to state that in their especial line we have not seen them surpassed, and rarely equalled.

There is a good display of instantaneous transparencies this year. Mr. Breese has two tables, each with eight stereoscopes, containing his exquisite transparent slides, with rare moonlight and sunset effects, and breaking waves, which, for absolute instantaneity, we have rarely seen equalled. Mr. Fry has a table with very fine transparencies, some of which are equal to those of Breese, but do not receive so much justice from being exhibited in inferior stereoscopes. Mr. Blanchard exhibits some of his charming pictures as transparencies; but these, like those just mentioned, suffer from the stereoscopes in which they are exhibited. Some of the same slides shown in a column stereoscope, exhibited, we believe, by Mr. Hare, are seen to much greater advantage. Messrs. Ferrier and Soulier exhibit a number of instantaneous and other transparencies of most exquisite quality.

A number of the very fine photographic enamels of M. Lafon de Camarsac are exhibited. Some very good photographs on porcelain, or enamel glass, are exhibited by Mr. Portbury. These, with the charming photographs on silk, by Mr. Cooper, are the only departures from the usual routine as to the basis of the picture.

The room devoted to pictures by French photographers, contains many valuable illustrations of processes, amongst

which we may name Corbin's dry collodionized paper process; Poitevin's and Fargier's carbon processes; Poitevin's photolithographic process; Negre's photo-engraving process, &c. The specimens of the latter are accompanied by some of the plates, and are not only interesting as illustrations of processes, but very excellent as results. M. Lemerrier exhibits some very perfect photolithographs by Poitevin's process. These are so good, and possess so much of half-tone, that we should have been very glad to know something more about them, especially how many stones were employed in producing the charming view of Alpine scenery. M. Charavet's specimens of carbon prints, by Fargier's process, hung beside the silver prints from the same negative, are exceedingly satisfactory. It is true, they lack a little of the brilliancy and transparency of the silver print, but they are, nevertheless, very excellent, as are also M. Lafon de Camarsac's specimens of the same process. The specimens of enlarging by M. Bertesh are exceedingly good: the detail is amazing, but either from the fault of the original lens, or that used in enlarging, the amount of distortion is very offensive.

We are here reminded that we omitted to notice in the proper place, a frame of carbon prints by Cecil Walker and Son, from being mis-classed under the head of collodion in the catalogue. These contain several specimens, which are very little, indeed, inferior to silver prints, and afford hope of the eventual possibility of obtaining prints entirely permanent without sacrificing delicacy or beauty.

A few specimens of apparatus are exhibited, but not such as call for especial notice. The exhibition is now closed, and there is, we fear, one drawback to its generally satisfactory character: it has not paid, and the sales have been small. The dull season, the out of the way position of the gallery, and a variety of other causes, have tended to bring about this result, which is, however, much to be regretted. The exhibition has been an exceedingly good one, and, on the whole, well managed, and, except financially, has, we believe, given general satisfaction.

COLLODION FORMULÆ.

THOSE who are in the habit of experimenting in the preparation of collodion will, probably, like to try the following formula communicated by M. Jeanrenaud to the *Moniteur de la Photographie*. To counterbalance the drawback of complexity which seems to characterize it, is the strong recommendation of the author, who possesses a high reputation. It is stated to give delicate results, to be very rapid and durable, improving rather than deteriorating with age. Here is the formula:—

Soluble cotton	8 parts
Pure ether	800 "
Alcohol sp. gr. 830	250 "
Iodide of cadmium...	9 "

Dissolve and add to 35 ounces of collodion 25 of pure bromine. To 3 ounces of the collodion then add 12 drops of strong liquid ammonia. A deposit is thrown down which may be re-dissolved by adding a few drops of glacial acetic acid. The three ounces are then added to the remainder of 35 ounces, and the whole left to settle for a fortnight. If it retain a straw colour, it is fit for use; if it be colourless, add a few drops of bromine.

M. Jeanrenaud also gives a formula for dry collodion as follows:—

Take ordinary collodion, and add to it 5 per cent. of a solution of ether saturated with yellow amber; the sensitizing bath consists of from 7 to 8 per cent. of nitrate of silver, and 2 per cent. of glacial acetic acid; the plate is then washed in four or five waters. The development may be effected either by the ordinary bath of sulphate of iron, or with pyrogallie acid. When the plates are large, it is necessary to fix the film around the edges by means of some varnish, either with alcohol or chloroform. M. Jeanrenaud found plates so prepared as sensitive, after

the lapse of a month, as when first fixed. The time required is about double that of the wet process, and for landscapes varies from three to seven minutes, according to the light and the season.

NEW FIXING AND DEVELOPING AGENTS.

BY M. MEYNIER.

1. Struck, on the one hand, with the danger incurred by photographers of being poisoned by the daily use of *cyanide of potassium* as a fixing agent, one of the most violent poisons that modern chemistry has produced; and desiring, on the other hand, to escape from the serious inconveniences presented by *hyposulphite of soda* of sulphurizing the proofs in the course of time, and of precipitating sulphur upon the slightest contact with any acid, I have searched among the chemical salts to find one which, without having properties injurious to the health, possessed the useful qualities in photography, as fixing agents, of the hyposulphite and cyanide above mentioned. I have been more successful than I anticipated, for I have found a salt which accomplishes the object in view in the most complete and satisfactory manner: this salt is the *sulphocyanhydrate of ammonia*, which hitherto has not been manufactured, nor for which has any use been suggested. This salt must be employed in the following manner:—To fix direct negatives and direct positives upon glass, a solution is made of the strength of 30 per cent. in pure water, and when the proof has been washed, a quantity of the solution is poured over it sufficient to cover it. The salts of silver unacted upon by light disappear from the proof as by magic, which assumes an opaline aspect, and upon being again covered with the solution, the proof is washed and remains perfectly fixed.

To fix positives on paper we employ a weaker solution of the strength of 12 per cent. only. The proofs being washed upon removal from the toning bath, are immersed in a dish containing the solution of 12 per cent., and allowed to remain in it five or six minutes, and then removed to a dish containing clear water. The water becomes thick; the proofs thus washed are again placed in a second bath of the solution of 12 per cent. and left in it for two or three minutes, then withdrawn and submitted to a methodical washing as when hyposulphite of soda is employed.

2. Every photographer who has employed sulphate of protoxide of iron as a developing agent, is well aware how quickly this salt is decomposed by contact with air. They have also experienced the inconveniences arising from its developing the picture unequally, of spotting and fogging, without it being possible to foresee such results. I have sought for a salt of iron, which, while it possessed all the developing properties of the sulphate, was exempt from its defects, and I have found that the *double sulphate of iron and ammonia* possess all the useful properties of the simple sulphate without having any of its objectionable qualities; it is unchangeable in the air, it develops the photographic image completely, and what is still more important, it requires a shorter exposure in the camera.

It is employed in the following manner. I dissolve 5 drachms of the salt in 100 drachms of water, and add to the solution 20 drachms of dilute acetic acid at 8° and 10 drachms of alcohol at 36°. The solution is employed in the usual manner.*

Upon this communication M. Davanne makes the following observations.

I have this morning tested in my laboratory the two substances which M. Meynier proposes to employ in photography.

The double sulphate of protoxide of iron and ammonia, dissolved in the proportion of 5 drachms of sulphate to 100 drachms of water, 20 drachms of pyroligneous acid and 10 drachms of alcohol, developed negatives with perfect detail and uniformity. The time of exposure was only twenty

* We have recently made trial of this double salt, see paragraph on last page.—Ed. P.N.

seconds for a portrait of medium size made with an objective of 4 inches diameter: nevertheless, the proof came out well, full of detail in the shades; and if there be not, as I am, however, tempted to believe there is, acceleration in the time of exposure, I can say that this developer acts as rapidly as the ordinary solution of sulphate of iron in the best conditions. It has an advantage over the latter in not being decomposed under the influence of the atmosphere, the double sulphate of iron and ammonia being much more stable than the ordinary sulphate, and, therefore, admits of a more precise formula.

The sulphocyanhydrate of ammonia has also been tested as a fixing agent:—Firstly, for negatives, employed in a saturated solution, it was sufficient to pour it upon the negative to perceive the layer of iodide of silver disappear as rapidly as when we employ for the same purpose a solution of cyanide of potassium of the strength of 3 per cent.; but it presents the advantages over the cyanide of not being poisonous, of not exhaling the cyanhydric odour, and if the negative has been badly washed and still retains salt of iron, instead of the greenish blue film which is precipitated on contact with the cyanide of potassium, sometimes straining the pictures, we only see the liquids take a red blood colour which disappears upon being simply washed.

I have also experimented with the sulphocyanhydrate of ammonia for fixing positive proofs; this substance is an energetic solvent of the salts of silver, and I feared to see that it would act like the cyanide of potassium in corroding the proof; but such was not the result, this fixing agent respected the half tones as much as the hyposulphite of soda does, and appeared to act like it in the different phases of the fixing; the proof must, however, be toned deeper than usual, because it more readily returns to its red colour. This first experiment at fixing, made hurriedly, under unfavourable conditions upon positives which had been some time printed, has, nevertheless, sufficed to show that we can succeed with it, and I think that by studying it carefully, we may obtain as good results as with hyposulphite of soda, over which the sulphocyanhydrate of ammonia presents the advantage of not giving spots while fixing, and especially of not giving free sulphur, which seem a guarantee of permanency for photographic positives.—*Bulletin de la Société Française*

ON THE DECOMPOSITION OF TANNIN PLATES.

BY STEPHEN P. LEEDS.

At the last meeting of the Photographical Society I presented to the notice of the members some tannin plates, which were prepared in the latter part of April last, strictly according to Mr. Russell's process—with the exception that the plates were coated with albumen, diluted with 3 parts of water to 1 part of albumen—and which were taken by me to Mexico, and exposed there in the camera, during the months of August and September, and brought back to this city, and developed during the present month. These plates presented such a novel appearance upon being developed, that I deemed them worthy of exhibition, in the hopes that the mystery of their strange appearance might be explained.

Throughout the surface of the plates, there appeared ring-like spots, some not more than one-tenth of an inch in diameter, while others were about half an inch in diameter. These spots were nearly clear after development. At first I was inclined to attribute the defect to the developer, but the otherwise perfect character of the negative at once refuted any such theory. That the plates were perfectly prepared, is proved by the fact that some of them were tried previous to my departure, and were found to be free from blemish, and to work well. Also that one of them was exposed in Mazatlan, and developed on the same day, and was perfectly clear and clean. Some of those which remained undeveloped were placed in the hands of some of the members of the Society, and under their treatment pre-

sented the same appearance; in one case, rather more so, than those which were exhibited by me.

I have arrived at the conclusion that a decomposition of the coating of the plates takes place after exposure to light, and that when the development is delayed for too long a time, the decomposition will have progressed far enough to ruin the negative. The plates should, therefore, be developed as soon after exposure as can be conveniently done. The time that can be allowed to elapse between exposure and development, without deterioration of the plates, depends upon so many contingencies, such as power or force of light, quality and condition of plate and temperature, and dryness, &c., &c., that no fixed rule can be given for it; but I think that not more than ten to fourteen days should ever be allowed to elapse; although I have known plates kept successfully six weeks before development.

I have deduced the above conclusion from the facts, that the plates when first prepared and tried proved good; that the plate, which was exposed, and soon after developed in Mazatlan, also proved good; while those in which the development was delayed for a long time, were all spotted.

Two rules may be safely followed—in fact they *should* be, viz:—

1st. That the plates, when exposed in the camera, should be entirely free from moisture.

2nd. That after exposure no more time should elapse than is unavoidable previous to development.

I am apprehensive that the moisture of the climate may have dampened the plates at the time of exposure.

Why the decomposition should have taken this peculiar form, instead of pervading the entire surface of the plate, and what is its primary cause, are subjects I am now investigating, and should my experiments lead to anything conclusive, you shall have the results.

I shall leave for Mexico in a few days, and shall take a good supply of tannin plates with me, and shall watch this matter with very close attention. There is difficulty in the way, somewhere, and, if possible, I will ferret it out.

In the hope that these few hints may lead others in the right direction, and perhaps elicit an expression of their views upon this, so important a subject, I leave the matter with a promise to refer to it at my earliest opportunity.—*American Journal*.

ON COMPOSITION PHOTOGRAPHS.

WHEN will the world become wiser on the subject of photography? Perhaps of all arts the photographic has been the one most misunderstood, and the one on which the largest portion of ignorant criticism has been written. In its earlier days, portrait-painters took fright at the facility it possessed of affording a really truthful representation of life, and, fearing their own art would suffer, did all in their power to decry the latest-born of science, and abused it as a mechanical method of producing a map of the face, having no power of giving a life-like presentment of the human face divine. The beautiful results exhibited by our best professors have, in some measure, removed this erroneous impression from the mind of the public, and the press has tardily given way in this matter to the voice of the many; but it is still curious to notice the rabid manner in which some of the writers of criticism in the daily papers oppose the introduction of fine art into photography: they still speak of the camera as an unthinking machine, forgetting that the machine, as the brush of the painter, is guided by the will of the operator. As a specimen of this kind of criticism, one may mention the review of our present Exhibition by the *Daily News*. The writer says—"If there is a development of the photographic art more offensive than any other, it is that in which the aim is to make a subject-picture by 'arranging,' as the phrase is, so many properties and living lay figures as a picturesque composition. There is one particularly conceited attempt of this kind (166, 'Bringing Home the May') by

Mr. H. P. Robinson, to which a verse of Spenser is appended. It is a large photograph, with women and children dressed up in country clothes; but the May, intended to be as beautiful as the real flower, is a ridiculous-looking stuff, more like sponge than hawthorn-blossom." Any of our readers who have seen this elaborate composition, which occupied the thoughts of the artist for many months, will see the absurdity of the paragraph we have extracted. The latter part of it is particularly funny. We have good reason for knowing that the "May" photographed in the picture was *not* an artificial "property," as the writer evidently thought, but some of the finest in Warwickshire (a county celebrated for its hawthorn), gathered in an unusually good season.

But, after all, we must not expect too much from a writer of this kind—one who probably has not time to think, but allows his brain to become, like his own idea of a camera, a mere machine, and runs off his "copy" mechanically, to fill a certain amount of space. But it is different with a writer who professes to have an intimate knowledge of photography, and who has written on the subject for many years. In our last number we printed a paper read before the Photographic Society of Scotland (a Society distinguished for its appreciation of art-photography), by Mr. Sutton, in which he deliberately states, "The first chalk-drawings of a schoolboy upon a wall are, in my opinion, more admirable, from the human interest which they possess, than the finest view of inanimate natural objects upon the ground glass of a camera obscura."

This, we take it, is rank heresy. We are not writing with the object of confuting Mr. Sutton's strange expression of his taste. We think we should only be insulting the intelligence of our readers, did we point out and attempt to prove logically that a fine view, as seen in a camera is much more beautiful than a schoolboy's caricatures. Our object is to express our deep regret that the higher branches of our charming art should be so misunderstood and abused by a gentleman who has earned the respect and esteem of all photographers by his many valuable inventions for facilitating the practice of the art-science. Mr. Sutton confesses that his opinions often change; let us hope that they will experience yet one more variation in favour of the art he now writes so vigorously against, and that they will then remain permanent.—*Photographic Journal*.

THE APPLICATION OF PHOTOGRAPHY TO THE MAGIC LANTERN EDUCATIONALLY CONSIDERED.

BY SAMUEL HIGHLEY, F.G.S., &c.*

DISCUSSION.

Mr. CHARLES JONES, as an old member of the Society, expressed the deep interest he felt in the subject which had been so ably brought before them this evening, and the pleasure with which he had listened to Mr. Highley's paper; and he congratulated the meeting upon the very practical manner in which that gentleman had treated the subject. Since the year 1859, he (Mr. Jones) had devoted a great deal of attention to photography in connection with the lantern, and the members would probably recollect that on two occasions, at the Society's conversazioni, he had exhibited a series of photographic transparencies in the lantern, showing its capabilities as an educational instrument. Amongst other subjects of a popular character, he had recently photographed the engravings given in the *Illustrated London News*, representing various incidents connected with the distress in Lancashire, and he should feel obliged to Mr. Highley if he would be kind enough to include a few of those photographs in the illustrations with which he was about to favour the meeting.

Mr. HIGHLEY said he should be most happy to do so.

The CHAIRMAN then suggested that he thought it would be more convenient that the illustrations should now be shown,

and any further discussion upon the paper would take place afterwards.

Mr. HIGHLEY then exhibited, on a large screen, an extensive series of lantern views of scientific subjects, illustrative of the application of photography to the representation of geological, botanical, zoological, microscopical, astronomical, geographical, ethnological, biographical, and pathological subjects; and afterwards examples of the representations of the artistic works of Kaulbach, Schnorr, and Hogarth; together with groups of sculpture, as well as some specimens furnished by Mr. Charles Jones.

The CHAIRMAN said it was now his duty to recall the attention of the meeting to the subject which had been so ably brought forward in the paper, and to invite discussion upon it. After the illustrations they had just seen, he thought they would be better able to appreciate the paper which Mr. Highley had read.

Mr. PEARSALL thought the medical profession and society at large would be greatly benefited by the application of photography to the illustration of the various stages of the diseases of the human frame. He had frequently been called upon to make sketches of the progress of disease, but it was impossible for an artist to follow the rapid changes which sometimes took place in cases of a complicated character. In this respect, therefore, photography was of the greatest value. Its importance to the palæontologist was also manifested in the illustrations given of the restorations of extinct animals. With regard to the illustrations of the distress in Lancashire, he thought it was a remarkable proof of the perfection to which the art of wood engraving had been brought, that the subjects exhibited this evening bear the severe test of the high magnifying power to which they had been subjected in the lantern.

Mr. W. HAWES thought so interesting a paper as this ought not to pass over without a few more observations than had already been made upon it; for he thought very few would have had an idea of the importance of this subject in an educational point of view, had they not seen the illustrations which had been shown, and undoubtedly they would not have been in a position to discuss the merits of the paper, or to appreciate the views enunciated in it, without first seeing the illustrations by which it had been accompanied. When they considered that photography itself, as an art, was scarcely a dozen years old—that it was only just previous to the Exhibition of 1851 that it was first practically applied—it was a striking illustration of the marvellous rapidity with which knowledge of all kinds was made available, and how soon it became popular and was turned to really useful account. It was only by the untiring industry of comparatively few persons, who had devoted themselves to the study and development of this new art, that it could have been brought to such perfection as to allow of the production of such beautiful specimens as had been exhibited this evening. He thought their educational value could hardly be over estimated, and that those present were much indebted to Mr. Highley, not only for the paper itself, but for the illustrations of this beautiful art with which he had favoured them, and which showed the vast amount of benefit which would be derived from photography applied to educational purposes. He could not conceive anything more valuable to the lecturer and teacher than this power of reproducing the marvellous creations of Nature, and exhibiting them in the way they had seen this evening. He therefore hoped that they would unanimously thank Mr. Highley for bringing this subject before them.

The CHAIRMAN said, before they adjourned, he might be permitted in the name of the meeting, to thank Mr. Highley for the interesting paper he had read, as well as for the illustrations of it he had given. As an educationist, a line which he (the chairman) had himself taken, he could not thank him too highly for the manner in which he had brought the subject before them, connecting it, as he had done, immediately with education. The microscopic illustrations exhibited had shown, in a remarkable manner, how the valuable sources of information opened up to us by that instrument might be popularized, and rendered available for general instruction. As an educationist, he (the Chairman), would again thank Mr. Highley most heartily, for he thought they had arrived, happily, at the day when they did not regard education as a mere matter of form. The eye must be entertained, and they might in many ways contribute to education and enlarge the powers and faculties of the mind without treading merely those old and narrow paths to which education has been hitherto confined. The rule of thumb was no longer admissible as a simple means

* Concluded from page 105.

by which alone education could be conveyed; and any means by which science could be popularized was to every educationist, in 1863, the most valuable assistance that could be given. He therefore looked upon photography as a means, and a most important one, by which opportunity would be afforded of enlarging and educating the minds of the people. He now begged, in the name of the meeting, to thank Mr. Highley both for his paper and for his beautiful illustrations.

Mr. Highley exhibited some transparent and other stereoscopic views of Geological and other Natural History subjects.

COPPER-PLATE PRINTING BY PHOTOGRAPHY.

A DISCOVERY has been made by which copper plates for printing on a type press can be made by a photographic process. These plates are precisely the same in appearance as the stereotypes taken from wood-cuts, and are printed from them in the same manner. The process of making these plates is patented, and, without entering into intricate chemical details, is somewhat as follows:—The negative used is either taken photographically from the object to be represented, if an engraving or a pen-and-ink drawing, or it is drawn with a steel point upon a glass plate prepared for the purpose. These plates are perfectly white like porcelain, and, placed upon a dark ground, say a black cloth, every line made upon them appears black. Artists work upon these plates with the same facility as with a pencil upon Bristol board. The negative being ready, it is placed in the ordinary photographic printing frame, upon what is called a matrix plate, against a glass plate covered with a thin coating, hardly to be distinguished from the glass itself. This matrix plate is thus exposed to daylight under the negative, and when taken out presents a beautiful brown positive picture upon a straw-coloured ground. It is then immersed in fluid, and when again taken out forms a bold bas relief, the reverse of a wood-cut. To procure the plate itself in copper, it is only necessary to cover the matrix with a thin metallic coating, and attach it to the positive pole of a galvanic battery in the usual manner of making stereotypes from wax, plaster, or other molds. As soon as the deposit is sufficiently thick, the copper plate is separated from the matrix and backed with type metal, ready for printing. These plates, for illustrations of books, for pictorial papers, copies of engravings, &c., are produced at a price from 40 to 50 per cent. below that of wood-cuts. It is hardly to be estimated what revolution this invention will produce in the business of publishing and engraving, but it is supposed by those acquainted with the subject that, so far from injuring the engraving interest, it will benefit it by creating a larger demand for all kinds of pictorial illustrations, wherein every available talent will be employed. The American Phototype Company are now using this interesting discovery.—*Humphrey's Journal*.

Proceedings of Societies.

LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting was held in King's College, on the evening of Tuesday, the 3rd inst., Mr. GLAISHER, F.R.S. in the chair.

THE SECRETARY having read the minutes of a previous meeting, the following gentlemen were elected members of the Society:—Messrs. W. Stokes, R. H. Allan, W. Cooke, G. J. Keet.

THE CHAIRMAN then called attention to various matters of interest to members, amongst which was a medal in wax of the reverse of the prize medal of the Society; some prints on paper prepared with india-rubber, by Mr. Cooper, possessing very pure and engraving-like blacks; some enlargements, we believe, by Mr. Warner, of Ross, and a couple of panoramic pictures taken on a flat plate with a common sixteen shillings lens, and including an angle of 120° with all the lines straight. The exact method was at present a secret, but would be published as soon as the patent was completed.

MR. SHADBOLT thought the Chairman was in error in sup-

posing all the lines straight, as those of the road were palpably curved. Nine months ago a gentleman showed him a positive picture which included an angle of 380°, going completely round the circle, and 20° over. He would bring the picture to the next meeting.

THE CHAIRMAN called attention to some circulars on the table announcing the forthcoming exhibition of the French Photographic Society, and remarked that he wished to reassure English photographers regarding the safety of any prints sent there, as some statements exciting distrust had gone forth. The names of the gentlemen constituting the Committee, and which were appended to the circular, afforded full assurance of the proper management of the exhibition.

THE CHAIRMAN then called attention to the handsome trunk camera which Mr. Meagher had given for sale in behalf of the Lancashire Fund, and which had not yet been sold. It was an excellent camera and a worthy object. There was another camera on the table of French manufacture, by Rollo, which possessed many advantages, and was very useful for copying.

THE CHAIRMAN next called attention to a curious illustration of the persistency with which an image sometimes remained on the plate, the outlines here being quite apparent after film was removed and the plate cleaned. It was in fact what might be called a spirit photograph. He also called attention to some card pictures which Mr. Wharton Simpson explained were the alleged spirit photographs produced in America.

A bottle of the double sulphate of ammonia and iron, prepared by Messrs. Horne and Thornthwaite, after the suggestion of M. Meynier, was examined.

THE CHAIRMAN announced that a portion of the presentation prints of the late Prince Consort, by Mr. Heath, were now ready and would be distributed by ballot. The remainder would be ready for distribution shortly, as Mr. Vernon Heath was printing them at the rate of about 50 per month.

MR. JOHNSTONE then read a paper "On the Electrical Theory of Photography."

THE CHAIRMAN, in proposing a vote of thanks to Mr. Johnstone, said he understood from the paper that Mr. Johnstone regarded chemical action as the visible exhibition of electrical action. It might be so, and it was possible the direct contrary was the case. Mr. Johnstone had, however, given considerable attention to the subject, and had very kindly come from Birmingham to explain his views, and he felt assured the meeting would willingly accord him its best thanks for his kindly feeling and earnestness in doing so.

MR. DEBENHAM then called the attention of the meeting to some experiments he had made with ammonia fumes upon excited albumenized paper—a subject to which he had given considerable attention. It was alleged that it would print in less time, and that the tones would be deeper and richer. In order to try it fairly he divided a piece of excited paper, and fuming one half, left the other as it was. He then placed the pieces side by side in the printing frame, under a double negative, both sides of which possessed equal intensity. This he had done repeatedly, preserving all the conditions as equal as possible, so that the effect of fuming might be distinctly marked. He had brought with him a negative and prints so produced for the examination of members. He had come to the conclusion that there was not the slightest advantage gained. At first, during the process of printing, the advantage seemed on the side of the fumed paper: it seemed to print with a deeper, warmer tone. But when both had been exposed for the same time, and both had been toned and fixed, he could scarcely distinguish the one from the other. Then there was a great disadvantage in the fact, that the paper would not keep, but discoloured considerably in the course of a single day.

MR. HUGHES, after making some observations on Mr. Johnstone's paper, and the importance of obtaining more certain knowledge of the principles upon which photogenic action was based, referred to the subject of ammonia fuming, and expressed his surprise that a good deal of space had recently been occupied in the journals discussing to whom the suggestion of fuming with ammonia was due, before it had been proved that the suggestion was worth following. It had been tried in his establishment without any advantage whatever, and had been voted by his people to be a useless bore.

MR. MALONE said the question of fuming was one purely of manipulation. The points to be settled were, what was the combination of ammonia with silver, and what were the effects of the combination in printing. These should be settled before discussing whether it was better to apply the ammonia by fuming, or by adding it

to the silver solution. When the ammonia-nitrate of solution, as proposed by Dr. Alfred Taylor, was used for plain paper, it was found to be more rapid, and give better results as regarded tone. As regarded the question of sensitiveness it was his conviction that it was decidedly more rapid than silver without ammonia. As to its value in regard to tone, since the introduction of gold toning that might possibly be altered, but with the old system it gave better tones. Then as to its mode of action, that was not well understood; and it was questionable whether the common theory expressed all that took place. It was quite possible that silver replaced a portion of the hydrogen as in cuprammonium copper replaced a portion of the hydrogen. In any case the subject demanded further experiment before it was condemned. He had recently tried the effect of a somewhat complex mixture consisting of ammonia added to solution of silver, and then nitric acid added until there was a faint acid reaction, and he liked the results better than with silver alone. He then proceeded to make some remarks on Mr. Johnstone's theory, observing that it was based upon conjecture only, and was not supported even by analogical facts. It was not, he thought, so well supported as the theory of the older chemists to the effect that the action of light was to split up the haloid salts of silver into their respective elements, forming chlorine, iodine, or bromine and metallic silver; and that in the case of a latent image that action was really commenced, though unseen, and was completed by the developer. This view was strongly corroborated by the experiment of Mr. Claudet in which he found that sufficient exposure of an iodized plate gave an image of metallic silver.

Mr. SHADBOLT asked if he rightly understood Mr. Malone to say that the action of light upon iodide of silver had produced a visible image without the presence of bromide or mercury?

Mr. MALONE.—Yes.

After a few words from Mr. Johnstone,

The CHAIRMAN said that Mr. Vernon Heath would read a paper at the next meeting "On the Progress of Photography in France."

The proceedings then terminated.

THE PHILADELPHIA PHOTOGRAPHIC SOCIETY.

THE second meeting of the Photographic Society of Philadelphia, was held at their new room in Walnut Street, and was quite crowded. The President, Mr. CONSTANT GUILLOU, presiding.

A portion of the time was devoted to the consideration of some amendments to the constitution, and to the election of new members, of which a long list had to be balloted for. Mr. Charles Waldack, of Belgium, and Mr. Robert Shriver, of Cumberland, Maryland, being elected corresponding members.

The report of the publication committee being acted upon, and there being no papers on scientific matter to be read,

Professor EMERSON said he wished to call the attention of the meeting to an article in one of the French journals, by M. Jacquemot, on the subject of the gradual fading of the impression of tannin plates, when their development had been delayed many days, and ascribing the cause to some molecular change in the film; he reviewed this theory, and also the theory advanced by Mr. Maxwell Lyte on the imprisonment in a thick film of the luminous impression. He stated that in his own experience there was no fading of the impression if the plates were protected from the action of the atmosphere; that in all cases of such fading he thought the truth should be ascribed to some atmospheric action on the plates, and that had they been kept from the air, they would have yielded good negatives even if months should intervene between the exposure and the development.

Mr. FASSITT had tried the experiment of exposing one-half of a plate one time, and then after the interval of a month exposing the other half—at the same time of day and with the same quality of light—and that the recent exposure developed better in every way than the other half, which was generally good in detail but lacking intensity.

Professor FAIRMAN ROGERS related his own failure in working the dry processes on very long journeys, but was doubtful as to the cause of his failure; but he would remark that he had never been so successful with tannin plates as he had been with malt.

The PRESIDENT spoke in high terms of the malt, and said that he had some malt plates at that time one year old.

Mr. FASSITT was sure nothing could work better than the

malt had in his hands, and he was often surprised at himself for having abandoned it for the tannin. He had just exposed a plate thirteen months old, and it was as good as when first prepared.

Professor ROGERS liked the malt for its simplicity; in his way of working he did not wash the plates after sensitizing, but merely drove off the entire silver by flowing the malt solution on and off.

Professor J. FRAZER said the water in our city after rains was in his opinion bad enough to cause all kinds of trouble, and the mud would be as bad as the dust would be. He recommended the use of filtered water.

Professor ROGERS agreed with him; but in his own case, he cleaned his water by subsidence in a large tank in the upper part of his house.

COLEMAN SELLERS had tried tannin plates washed when the water was not very clear, and he did not find any trouble from the mud. The water after rains being mere surface water is generally rather softer than when the rivers are clear, but low, and are supplied by springs. He begged leave to call the attention of the meeting, while on the subject of dry plate photography, to an experiment recently tried by Mr. Borda, who was not present to relate it himself.—

Mr. Borda had desired Mr. Hull, of New York, during his recent visit to this city, to expose two plates on the same view, one of which was to have his usual exposure, or such as his judgment should say it would require, and the other to have only thirty seconds. The first was exposed five minutes. This long exposed plate was to be developed on Mr. Hull's return home, hence we know not how it turned out. But the short exposed plate was treated by Mr. Borda in the manner suggested to him by Mr. H. T. Anthony, viz., toned with weak ammonia before development. He demonstrated on this plate that by careful manipulation and the use of a weak developer, little silver and considerable excess of the retarding acids to overcome the alkalinity of the film from the toning, the development would be protected for at least one hour and yet no tendency to fog, and his experiment resulted in a negative somewhat under-exposed it is true, but with a very intense sky and all the detail, excepting in the foreground well defined; one minute exposure would have given him a good picture. He had not done this to advocate short exposures, but to demonstrate the practicability of the toning process, and its advantages.

Professor ROGERS read a letter of inquiry as to the practicability of printing with the solar camera by artificial light.

Mr. WENDEROTH being appealed to, said he had made many such pictures, but all by development; and that an exposure of six minutes was needed in cases where he could have printed on the same paper in the same light by superposition in about one second. He had always preferred the developing process even for sunlight, but did not practise it now owing to the difficulty of instructing others how to work, and the work attending careless manipulation.

During the evening Professor Emerson exhibited some of Mr. C. Breeze's glass stereographs, which he had brought with him from England. They were greatly admired.

Vice-President SERGEANT exhibited a specimen of resin paper printing, from England, which may not have been a fair specimen, but was not considered of any value at all.

M. LA FETE exhibited his Jaminiscope, and, much to the admiration of the members, explained its *modus operandi*.

COLEMAN SELLERS displayed two sizes of the Harrison and Schmitzer globe lens, and exhibited specimens of work done by them; also in contrast a specimen of the work of the Grubb aplanatic lens, which is said to include a visual angle of seventy degrees, but with considerable spherical distortion of the marginal lines, as was evident in the print shown.

Professor EMERSON presented the Society with one of his stereoscopes, and received the thanks of the Society for the gift.

It was resolved that the room should be open every Wednesday evening, for informal conversational meetings.

The meeting then adjourned; but the members were so interested in general conversation, and there seemed so much harmony and good feeling among all present, that it was late before they retired, all well pleased with the beginning of the infant society.—*American Journal*.

Correspondence.

IODIDES AND BROMIDES IN COLLODION.

DEAR SIR,—The leading article of your issue of the 24th October last somewhat alarms me; but, I really hope you do not mean to close the discussion.

I am aware that I need expect no mercy, for I am contesting a widely received principle, and, thereby, placing myself in direct antagonism to a large section of photographers. But I believe that you will give me one more opportunity to be heard, because of "the earnestness and manifest honesty" which you have handsomely attributed to my exposition of the question of "iodides and bromo-iodides." Your claim "to do full justice to all sides of all photographic questions" cannot be disputed, and its enunciation, particularly, makes me bold to avail well of the opportunity you will now finally afford me of defending myself from misconception on the one hand, and of pointing out error on the other.

You pronounce my first error as having "misappreciated the avowed character of Mr. Blanchard's experiments," and explained that those experiments were held "tolerably conclusive of the fact, that bromides and iodides, in combination, were more sensitive than either bromides or iodides alone."

I was well aware of this, provided, that by "iodides alone" is meant ammonium, or potassium, or magnesium, and no other; for, at page 479 of the PHOTOGRAPHIC NEWS, I remarked as follows:—"They (Mr. Blanchard's experiments) were simply illustrative of the circumstance, that, under certain conditions, which nobody should adopt, bromo-iodized collodion is superior under iron development to simply iodized collodion."

You also remark, that, on the "general question," Mr. Blanchard's experiments were not put forth as conclusive." No admission could be franker or fairer, and I am sorry for having understood otherwise.

The "general question" (the exposition of which has never yet been attempted) I have endeavoured to show, involves the arranging against each other of an iodizer and bromo-iodizer made of one collodion, and constructed of like salts, and like combinations, *i.e.*, if the iodizer is compounded of ammonium and cadmium, or cadmium and potassium, the bromo-iodizer should also be made of the same salts, in the same proportion; only, that a part or all of one of the salts in the latter case should be a bromide; and that, if the iodizer is made only of ammonium or only potassium, or only cadmium, that the corresponding bromo-iodizer should be made of iodide and bromide of ammonium, or iodide and bromide of potassium, or iodide and bromide of cadmium, when, a comparison will show the iodizers invariably superior in every respect to their pair bromo-iodizer.

It is possible, nay, certain, that in the several combinations of cadmium and ammonium, or cadmium and potassium tested, that the bromo-iodizer of one experiment or pair will be superior to the iodizer of another pair; but this bromo-iodizer will in its turn be inferior to its pair iodizer. We can evidently, then, make iodizers and bromo-iodizers of various capacities (the cadmium being the regulator of durability and sensitiveness) alternately inferior and superior, until we come to an iodizer superior to the best bromo-iodizer, which will be at the same time the pair of that iodizer, and superior to all other iodizers and bromo-iodizers. And, above all, the pure cadmium iodizer will rank first. I have nowhere taken ammonium or potassium iodizers into account, because, for practical purposes, they can bear no comparison with the combination salts. I have shown the results of my experiments in a letter dated and posted a month ago to your address, under the head A to D, as also the comparative merits of pyro and iron development. An examination of the same will show that iron development stands first.

To show that the combinations of salts do possess the different degrees of sensitiveness and durability that I claim for them, I will place the matter in the following light.

Very sensitive ammonium and potassium collodion can be made. They are undisputable facts; for instantaneous work has been done with them, as with cadmium collodion, or with collodion salted with combinations of salts. But they (the potassium and ammonium iodizers) are so capricious as to render them a source of trouble. Hence cadmium collodion ranks first on the score of stability. Next to it we must place combinations of cadmium and ammonium, or cadmium and potassium, their order being regulated by the proportion of the

cadmium salt present in each, until we end with ammonium or potassium only. Now, all are equally sensitive.

But, for all practical purposes, how do matters stand? We cannot avail ourselves of each in its best condition; we cannot at will give to each the collodion most suitable to it; but we may at all times succeed in getting a collodion fit to be iodized with one or more of the combinations, and we can never better employ a collodion. Any collodion fit to be iodized, with potassium or ammonium alone, will admit of the introduction of cadmium more or less. Any collodion fit to be iodized with cadmium only will admit of any combinations of salts (which anybody may ascertain for himself in a moment) being used with it, although it will be worthless for ammonium or potassium alone. Any such collodion will therefore be the best to experiment with.

Now, cadmium glutinises collodion and attains maximum sensitiveness slowly, and it deteriorates slowly; but potassium and ammonium liquefy collodion—they attain sensitiveness quickly, and as rapidly lose it. Under these circumstances the effects of the alkaline salts upon the collodion are not so energetically injurious in the presence of cadmium as when employed alone; but injurious they still are in proportion to the quantity, and are comparatively innocuous when their quantity is small. I should therefore conclude that the smaller the proportion of the alkaline salts, and the greater that of cadmium, the less the injury to the collodion by the greater glutinosity opposed to the liquefaction: the greater the stability by the resistance to the deteriorating effects upon the collodion, and the superior the ultimate sensitiveness by the time given to attain it.

Only on one supposition, it appears to me, could there be an equality of sensitiveness in all combinations with any given collodion—if the alkaline and acid salts, apart from the question of stability, sensitize the collodion equally rapidly, and affect it identically; but this can never be the case.

As respects Mr. Blanchard's experiment with iodide of potassium on the one hand, and a bromo-iodized collodion on the other, made to test whether a potassium iodizer was the most sensitive, as claimed by some operators, I beg to observe that under no circumstances could the result be reliable, unless the comparative experiments (provided that the collodions and baths most suitable to the salts had been furnished) had been extended over a period such as would have included the best average condition of such collodion, as insisted upon in my last letter.

As regards equality of sensitiveness between all iodizers, I think there should be very little room for doubt if the exact condition of suitability of collodion and availability in the exact stage of sensitiveness—especially as regards potassium or ammonium collodion—are secured. For we read of instantaneous work by Count Montizon, Legray, Maxwell Lyte, &c., with the ammonium and potassium salts. No operator now, however, would so use them because of their notorious capriciousness and instability, and all prefer collodion salted with cadmium, or at least as half of the total quantity of salts, because stable and comparatively reliable.

As respects the exception I have taken to Mr. Blanchard's experimenting with one plate, two collodions, and two lenses, which you have thoroughly explained, I scarcely care to wish it to be decided (more emphatically than it has been done by you) whether the plan I recommend or Mr. Blanchard's is the legitimate one, and which of them is to be recommended for simplicity, and, above all, for unquestionable accuracy and certainty of result. For you already concur with me in the use of one lens, and, by implication, one plate and one collodion.

I think you agree with me that one collodion, iodized and bromo-iodized similarly, one lens, and light exposure are indispensable. I claim also one bath for each pair of iodizers and bromo-iodizers, but you contend that "a bromo-iodized collodion, for instance, works best with nitric acid in the bath; to a simply iodized collodion this would be fatal." To prevent the possibility of any misapprehension of terms here, I beg to inquire whether by "simply iodized collodion" you mean a collodion iodized only with potassium, or ammonium, or magnesium, or with cadmium and combinations including cadmium. If with the first three salts, I concur in part with you; but if with cadmium and combinations including it, I differ most emphatically from you.

All my experiments were made with nitric acid baths only; and in page 467 of the PHOTOGRAPHIC NEWS I laid down the following as a radical principle:—"The constitution of the

nitrate bath is no unimportant matter in experiments—one abound with acetate of silver and alcohol, &c., is the least desirable. The only one admissible is a pure, unadulterated bath, having had a little careful working. As the question of fused and recrystallized nitrate of silver is still in an unsatisfactory condition, the best salt from reputable dealers will answer; and as regards organic matter in water, let the liquid be cleared by light and oxide, and we shall have a good stable working bath, rectified with nitric acid and oxide.* And lower down, in the same letter, I have again alluded to the nitric acid bath. No where have I made mention of any other bath. Nothing can be plainer than this, and than the principles I have contained for in comparative experiments.

I am not the first to consider a nitric acid bath anything but fatal to iodized collodion. Mr. Thomas, of Pall Mall, years ago enunciated the superiority of the nitric acid bath over every other, and he made no distinction between any iodized and bromo-iodized collodion. To this day his collodion bottles have printed wrappers describing the construction of his normal bath. Another able advocate for nitric acid baths is Mr. Hockin. *Vide his Photographic Treatise.*

My experience of the several baths is as follows; and it is in the power of anybody to satisfy himself of its thorough correctness.

A nitric acid bath answers the best with cadmium collodion, or collodion containing cadmium as one of the salts. But the bath must wait for the ripening of the collodion, whether iodized or bromo-iodized, when it will give exquisite negatives free from spots and stains; but not more rapid results than those attainable with the same collodion in acetic acid, acetate of soda, or carbonate of soda baths, when these are in their sensitive condition. But the nitric acid bath is supreme in stability, *i.e.*, it is rectifiable and comparatively under control. It deteriorates slowly.

I do not, however, concur in the use of the nitric acid bath with ammonium and potassium collodions, newly iodized and bromo-iodized with those salts, or in their sensitive conditions. The other baths will then give by far the better negative. When, however, the said collodion is deteriorating, the nitric acid bath will give a finer detailed negative, and in a shorter time.*

THE FRENCH PHOTOGRAPHIC EXHIBITION.

SIR,—My attention has just been directed to a letter in the *Photographic News* of the 13th February, which contains a charge against the French Photographic Society, or rather against its secretary, to which the approach of the exhibition at Paris gives special importance.

I am confident, that, as a gentleman, Mr. Vernon Heath will, after reading the explanation, experience a regret equal to my astonishment, and he will admit, that if we had had the good fortune as to speak the same language and to do without the aid of an interpreter, we should have both been spared a very disagreeable affair. In fact, if I had not waited for his return, he would have received at once the explanation to which I am now obliged to give the publicity he has given to his note.

When last month Mr. Vernon Heath did me the honour to visit me at the French Society's establishment, with the gentlemen he had been so fortunate as to meet at Paris, he had, I was informed, two objects: first, the wish to present some specimens to the Society at their next meeting, and next, to reclaim some frames sent by him to the Exhibition of 1861. I gave to the first proposition, naturally, the flattering reception that it merited, and recollecting the frames exhibited by Mr. Vernon Heath in 1861, I said that if they had not been sent back at the close of the exhibition they had certainly been kept carefully at the *Palais de l'Industrie*, whether by error or for some other reason, which it was not possible, after the lapse of two years, for me to recollect at once; I promised, however, to go myself and see to the matter.

The following day, I believe Mr. Vernon Heath came again with the same gentleman to say that he was obliged to leave sooner than he expected, and could not be present at the meeting of the Society. Being much occupied by

business rendered urgent by my long absence in London for the exhibition, and not thinking that the departure of Mr. Heath would have been so precipitate, I had not gone to the *Palais d'Industrie* to make inquiries. I said I would go the same day, and did not doubt to find the frames if they had not been sent, and I could easily after his departure send them to London or elsewhere. I proposed at the same time to make in his name, the presentation, he regretted not being able to make himself.

The answer returned to me was, that this would be useless, as Mr. V. Heath's absence would be very short, and on his return he would certainly call on me.

The day after, I went myself to the *Palais d'Industrie*, and found that, in fact, the frames of Mr. Vernon Heath were placed with care among others for which, for their despatch, orders had not been received, or for which we had received contrary orders.

Mr. Vernon Heath, in his note, admits that I had informed him of the prolongation of the Exhibition, and asked him if he wished his frames at once, or with the others sent by France to the International Exhibition. He admits, also, telling me not to send them, as he had an agent at Paris. Now, did Mr. Vernon Heath, or did he not, give the order to his agent to fetch the frames, or were the frames to be sent to his agent? I cannot affirm positively, but, in either case, there could be nothing worse than a simple error.

Having understood seriously the answer that was made me, I waited innocently his return to give him these explanations.

As regards Mr. Robinson, the answer is still more peremptory.

When Mr. Vernon Heath and his friend spoke of Mr. Robinson's reclamation, and assured me that he had sent at the same time as Mr. Heath some photographs for the Exhibition of 1861, I answered that I did not recollect, and that he was probably mistaken. I recollect very well certain subjects and studies after nature, of which Mr. Robinson was the author, and which had figured in former exhibitions, but that he had not since exhibited at Paris. Despite the assertions to the contrary I find that I was right, for the catalogue of 1861 does not mention Mr. Robinson, but that of 1859 does mention him. Notwithstanding the time that has elapsed, I succeeded in getting traces of this affair, and here is what passed in 1859 on the subject of Mr. Robinson.

To be agreeable I put him in communication with a gentleman engaged especially in the sale of photographs. I knew nothing of him personally, but I had heard of Mr. Rarrere, 59, Rue Richelieu, and to him I mentioned the matter. He wrote to Mr. Robinson to send him direct the prices of his photographs. I had no reason to take further steps which might appear officious, so delivered to Mr. Rarrere the photographs of Mr. Robinson on his account, with the exception of two that were to be left with the Society as specimens. It is then to Mr. Rarrere that he should address himself, for it is no longer an affair of exhibition, but of commerce, to which, thank goodness, I am entirely a stranger. If there is negligence, Mr. Robinson has only himself to blame.

You see, Mr. Editor, how an uncharitable interpretation can alter and distort the most simple facts. I believed it right to enter into these details because, I repeat it, the circumstances give particular importance to a charge calculated to deter your countrymen from exhibiting at Paris.

The French Society, which counts amongst its members a great many foreigners of every country, has always shown in its actions the most liberal intentions, and has always shown and proved its good sentiments towards the Photographic Society of London.

As for me, its Secretary, I have certainly not the pretension to be perfect and infallible, nor yet to satisfy everyone, but I certainly do my best, so that the number of those who render me justice is sufficient to compensate for the annoy-

* The remainder of Mr. Webb's letter in our next.

ances entailed by my position. Anyone who has seen our exhibitions must admit that we have for the foreign exhibitors a care that our French exhibitors would be glad always to meet abroad.

To assure your countrymen, I can inform them that some of the best English photographers at the International Exhibition wished to exhibit in the French section for the only reason that they could depend upon my care and attention.

At the close of the International Exhibition, my honourable colleague, Dr. Diamond, Secretary of the London Society, informed me rather late of the special exhibition then contemplated and now or lately open. I thereupon gave orders to stop at once all packing, and took the necessary steps among the French exhibitors, notwithstanding the derangement and trouble both for them and myself. If through being informed too late the result was not so complete and perfect as I should have desired, at least I did all that was possible.

Now, sir, shall we be wrong in counting upon a just reciprocity? I do not believe so. Sir, I hope that this answer, published in your journal, will suffice to change the consequences of a charge which, I regret, I did not see earlier. I am persuaded the London Society will act as we would act under similar circumstances, and, with yourself, will do us justice. No, sir, I do not doubt it, for I have met amongst your countrymen many true gentlemen, and have considered the meeting to be simply natural and not an unusual piece of good fortune.

I count, sir, upon your honour for the prompt insertion of this answer, and beg you to receive the expression of my distinguished consideration.

M. LAURIER.

Secrétaire-Agent de la Société Française de Photographie, Rue Drouot, 11, Paris.

P.S.—Mr. Vernon Heath having an agent at Paris, ought to find it very simple and just that we expect him to send and take his frames, and I insist above all that he sees them in their actual state and admit that we take for our exhibitors precautions that are not always taken elsewhere.

The International Exhibition.

REPORT OF THE JURY ON PHOTOGRAPHY AND PHOTOGRAPHIC APPARATUS.*

3100 HORNE and THORNTWHAITE (H.M.) contribute a variety of cameras and lenses well adapted for general use.

Powell's registered stereoscopic camera, possessing the utmost degree of portability combined with efficiency. Schaw's camera is also well-suited for tourists: an instantaneous shutter on the principle of the guillotine is very ingenious and well adapted for its purpose. Various other articles are exhibited, all of which are characterized by general excellence. The chemical contributions are fine, and the specimen of chloride of gold is probably the finest in the Exhibition.

3111 LEAKE, J. C. (H.M.), is the inventor of a convenient and portable dark tent of very moderate price and considerable efficiency. The principle is simple and good, but the example exhibited had not been made with sufficient consideration to the temperature to which it would be exposed, being considerably warped and twisted by the heat.

3120 McLEAN, MELCHISH, and HAES (H.M.).—A variety of apparatus of general excellence is exhibited. Portable cameras made of metal for combining perfect rigidity with lightness and portability; Lieut.-Col. Shakspeare's simultaneous camera, in which an extra lens is attached to act as a finder, so that when a proper focus has been obtained by this lens, whilst the sensitive plate is *in situ*, exposure may follow immediately after, without the delay which is usual where the ground glass has to be withdrawn and the holder containing the sensitive plate inserted in its place.

A variety of lenses combining facilities for lengthening and shortening the focus, to render them suitable for landscape as well as portraiture, are also exhibited.

3128 MURRAY and HEATH (H.M.)—This firm, which has lately passed into the hands of Mr. Heisch, chemical lecturer at the Middlesex Hospital, exhibits apparatus of great excellence. A copying camera, with a variety of convenient appliances, and capital workmanship and material; camera-stands of bamboo cane, combining great height with lightness; a chemical chest, or portable laboratory, with complete equipment for use; Smart's dark tent, which affords considerable convenience as a portable dark room, is so fitted and arranged as to secure every facility for operators engaged in landscape photography; other apparatus exhibited by this firm combine all modern improvements in design with great care in the goodness of the workmanship.

3125* MEAGNER, P., (H.M.) exhibits a variety of cameras, camera-stands,

stereoscopes, &c., of very great excellence in design, material, and construction. The seasoning of the material is stated to have received especial care; the skill shown in the contrivances for the convenience of the photographer, and the workmanship and general finish possess much excellence. In addition to other modern cameras, Mr. Meagher exhibits a tourist's camera intended for stereoscopic pictures, or for plates 7 inches by 5; the body is of the bellows form, expanding from 3½ to 10 inches, being applicable for the short focus of quick-acting stereoscopic lenses or the Dallmeyer's triplet. Six dark frames accompany the camera, and the focussing-glass is attached—a great convenience in out-door operations. It is altogether a most convenient, economical, and portable instrument, very well adapted for the combined purposes for which it is intended.

Mr. Meagher is the manufacturer of the excellent cameras originally designed by Mr. Kinnear of Edinburgh; he manufactures largely for the dealers in first-class apparatus.

3129 NEGRETTI and ZAMBRA (Medal) exhibit a variety of photographic camera and stereoscopes of very great beauty in design and neatness of workmanship. In stereoscopes their specimens display great variety and elegance. The revolving stereoscope, exhibiting many slides in succession, is a very desirable application; other apparatus are also contributed by this firm. Reference will be made elsewhere to their beautiful transparencies and book illustrations.

3133 OTTEWILL, T., and CO. (H.M.).—This firm send samples of their well-manufactured cameras, consisting of folding cameras, trunk cameras for the operating-room, binocular and other stereoscopic cameras, together with many other useful photographic appliances.

3136 PONTING, T. C. (Medal).—A medal was awarded to this exhibitor for the excellence of his sensitive collodion, a reference to which has been made in speaking of Bland and Co., who exhibit samples of his manufacture.

3149 ROSS, T. (Medal).—A medal was awarded to Mr. Ross for the excellence of his photographic lenses. These include a variety of forms for different purposes, all of which are of very good quality. The portrait lenses comprise various examples, possessing great intensity, good definition, and great rapidity, yielding negatives of considerable beauty, prints from which are exhibited. The single landscape lenses are unsurpassed of their kind. A stereographic double combination is very rapid, and well suited for taking instantaneous views. The orthographic lens, constructed on the formula of Professor Petzval, is well adapted for the delineation of architectural subjects and for copying flat surfaces; all these lenses have their chemical and visual foci coincident, and on trial proved highly satisfactory, fully maintaining the reputation of a house which in 1851 received the only award for lenses especially manufactured for photographic purposes. The chief novelty manufactured and exhibited by Mr. Ross is a panoramic lens and camera, invented by a gentleman who has contributed many ingenious novelties to the art. It is novel in principle and results, giving pictures which include a lateral angle exceeding 100 degrees. Mr. Ross also contributes examples of a great variety of excellent apparatus in which the form and workmanship are of first-rate quality; they combine all the most approved appliances known and used in the art.

3150 ROUCH, W. W.—This exhibitor sends a series of valuable apparatus and chemicals.

A portable operating chamber, described as Edwards's New Model Tent, combining great portability with convenience and efficiency, differing in many of the contrivances of a similar character in the ample room afforded in the part immediately over the head of the manipulator, materially contributing to his comfort. Another well adapted portion consists of a small water-tank placed outside, a pipe from which, with spring tap, enters the tent at a convenient corner, being always at hand for the ready use of the operator. The tent is in every respect admirably contrived to meet the wants of the amateur photographer. Various cameras are also exhibited. A well-contrived portable laboratory; an instantaneous shutter; dippers for the bath of pure silver; and other photographic requisites. Mr. Rouch also contributes samples of bromo-iodized and other collodions made according to Mr. Hardwick's formula. A medal was awarded to Mr. Rouch for his series of small photographs, which are stated to be produced in the tent referred to, and with the same kind of collodion and chemicals he exhibits.

3155 SKAIFE, T. (H.M.).—Mr. Skaife is the inventor of an ingenious miniature camera described as a "pistolgraph," the productions of which he terms pistolgrams. The lenses are very small and exceedingly rapid, and well fitted to the production of very small instantaneous pictures, to which aid a clever instantaneous shutter is attached. The pictures are glass positives sealed between two pieces of glass, which are then ground by the lapidary, and fitted into mounts for various purposes. The representations are generally those of babies, and every phase of infatuate expression is accurately depicted by the means that Mr. Skaife uses.

3158 SOLOMON, J. (H.M.), exhibits, in addition to a good general display of apparatus, a great variety of excellent contrivances for the aid of the photographer, amongst which may be mentioned a cutting table on which to trim and shape photographs. It consists of a slab of thick plate glass, fitted on a frame, and moving on a centre; the glass slab revolves whilst the photograph and glass shape remain unmoved, which facilitates the operation and prevents the slipping or disturbance of the shape. Also a strong iron camera stand of great utility in the process of development; a new pneumatic holder; a collodion pourer which prevents the possibility of impurities ever falling on the plate; a dropping bottle on a good principle; a convenient dark tent, and a variety of other appliances; the whole showing considerable ingenuity and well deserving of attention.

3161 SPENCER, J. A.—Various samples of albumenized photographic paper. These papers are carefully prepared and salted in different proportions, to suit the purposes for which they are especially intended. Mr. Spencer manufactures very extensively for some of the leading firms in this country.

3157 WRIGHT, DR. H. G. (H.M.).—The complete portable apparatus combining a dark tent and all requisites for operating in the room or open air, which pack into a parcel easily carried by one person, was invented by Dr. Wright, a physician in extensive metropolitan practice, with a view to the facility with which it might be carried into the sick room and assist in the delineation of the various aspects of disease. It is equally well adapted to the purposes of landscape and stereoscopic photography. It is altogether a skilful and valuable contrivance.

AUSTRIA.

671 DIETZLER, C. (Medal).

679 VOIGTLANDER and SON (Medal).—These two names may with great propriety be associated, both having received Medals for the excellence of

* Continued from p. 106.

their lenses, and both basing their construction on the calculations of Professor Petzval. The lenses of Voigtländer are characterized in a remarkable degree by intensity and perfect definition on a mathematical plane. The lenses of these makers combine qualities which render them eminently valuable to the photographer.

— PONTI, CHARLES (Medal).—A Medal was awarded for a novel instrument styled the "alethoscope," invented by this exhibitor, by which very remarkable effects of relief and illumination are obtained. This instrument was only introduced into the Exhibition a few days before the Jurors closed their labours; they are enabled, however, to state that it will doubtless afford a new source of interest in the application of photographic pictures, and with a new object to amateurs in the art.

128 MOLL, A. (H. M.), displays a remarkably fine series of photographic chemicals, showing that much care has been used in their preparation, appearing to the jury well worthy of commendation.

(To be continued.)

Photographic Notes and Queries.

CRYSTALLINE DEPOSIT ON NEGATIVES.

DEAR SIR,—Having noticed an article in No. 223 of the PHOTOGRAPHIC NEWS respecting the crystalline deposit on negatives, and having myself occasionally been disappointed in taking views of any beauty whatever from that cause, I am induced to make the present communication to you on the subject, as my experience slightly varies from what I find stated in that article.

The size of plate I usually work is 10 by 8 (that being the most convenient size for India, where the thermometer is frequently over 100° in your dark tent), with a bath (glass, in mahogany case) containing about 50 or 60 ounces of bath solution; collodion, Bolton's and Thomas' mixed. With these I have taken as many as twelve negatives in one day, and that without a single failure; but a short time ago, wanting to take a view, and not having any collodion on hand but what had been either very recently or several weeks previously iodized, I chose the latter and went out. The first picture, however, that I took on fixing had a peculiar greenish appearance, and was slightly fogged, and when finished, looked as though it were covered with pin-holes; this rather puzzled me, but remembering that I had left the plate in the bath rather longer than usual (about 3½ minutes), and, thinking it might have resulted from that, I coated a fresh plate, only giving it one minute in the bath, and the result was that I got as good a negative as any I have yet taken; not understanding this, I tried again, leaving the plate in three minutes, when the negative, on finishing, presented the same defects as the first one did, and I found that I could, by changing the time for sensitizing the plate get either a good or bad picture with that collodion. Being struck with this peculiarity, I tried the next day again with similar results; but on using some new collodion, I found I could not affect it in that way, for no matter how long I left it, even to ten minutes, in the bath, the film was even and firm and perfectly satisfactory.

Now, I don't think this could have arisen from the supersaturation of the bath with iodide of silver, because the bath is nearly new, and the temperature never falls sufficiently low to cause it to crystallize; besides, it only affected the *old* collodion when left in the bath longer than usual. If it is owing to the collodion, how is it that it works well when only left a short time in the bath?

The only conclusion I could come to was that the pin-holes were caused by keeping the *old* collodion too long in the bath; but whether the fault was in the collodion or the bath I am unable to say, but should very much like to know if any person of more experience and knowledge than myself would kindly inform me.

Regretting that I have transgressed so much on your time and patience, believe me, yours faithfully,

AN ENQUIRER.

Court House, Bombay, January 26th, 1863.

[In the number of the PHOTOGRAPHIC NEWS to which our correspondent refers, there are two articles on the subject: one by Mr. Waldack, in which he refers the deposit to iodo-nitrate of silver; and one by ourselves, in which we trace it on some occasions to a different cause, namely, the formation of oxalate of silver. If our correspondent will read that article he will find that it is to the use of an old and somewhat decomposed collodion we refer this result. Leaving a plate long in the bath would, of course, give more time for its formation.—ED.]

ALKALINE TEST PAPER.

SIR,—It has occurred to me as an omission in many manuals of photography, and in the lists of "requisites" published by photographic chemists, that although litmus paper is given as a test for acids, no test is mentioned for alkali.

For this reason I think it probable that many operators may not be aware of a fact well known to chemists, viz., that a paper made from turmeric will detect the slightest trace of free alkali with as much certainty as litmus will detect acid.

A teaspoonful of turmeric should be boiled for a few minutes in half a pint of water; and when the decoction has been allowed a short time to settle, white blotting-paper should be soaked therein and hung up to dry. The paper will be dyed a bright yellow, which will instantly change to a red brown under the action of alkali.

A gold toning bath which would cause no alteration in the colour of either test paper (litmus or turmeric), would thus be perfectly neutral.

As there are many who would be glad to know of such a simple test, the above may perhaps be worth insertion. If you do not think so, pray put it in the waste basket, and oblige—Yours obediently,

W. CORRI.

East Greenwich, March 3, 1863.

[The use of turmeric paper is so familiar in chemical experiments, that it may probably have escaped especial mention, and is worth mentioning for the benefit of beginners, who will generally, however, find it better to use the reddened litmus for the purpose.—ED.]

AMATEUR PORTRAITURE IN THE OPEN AIR.

DEAR SIR,—I have the pleasure to send a few cartes de visite portraits for your inspection, being the result of following out the directions given in the NEWS and the NEWS ALMANAC, and showing what kind of portraits may be taken in the open air. They were done in the country the week before last, when the frost was on the ground. Perhaps a description of the way in which they were taken may be useful, as some amateurs are apt to imagine that portraits can not be produced except in the studio.

The sitters were placed against the garden wall, with a piece of canvas nailed against it for a background for full length picture; a piece of coloured calico was nailed on one side of the background for a curtain, and a bit of carpet placed on the ground, a chair and table completed the accessories. The plates were prepared and developed in a Smart's tent set up in the garden. The lens used was Dallmeyer's No. 1 B lens with the X stop for vignettes and the next size smaller for full length pictures. The collodion was made with pyroxyline according to the formula in the NEWS ALMANAC. Ether and alcohol methylated, a 50 grain nitrate bath slightly acid with nitric acid; developer, iron, 30 grains; acetic acid, 15 minims; water 1 ounce; alcohol, 20 minims; intensified with pyro, 2 grains; citric acid, 1 grain; water, 1 ounce; fixed with cyanide, 8 grains to the ounce of water.

I am sorry that printing is not better, but it was done away from home, and, therefore, rather carelessly. They were toned in Lacy's bath as given in the ALMANAC.—I remain, dear Sir, yours faithfully,

N. L. NOVERRE.

[The portraits received form a very interesting illustration of what may be done by the amateur with a little judgment and contrivance, without the manifold appliances of the professional portraitist; some of the specimens surpassing those produced "with all appliances and means to boot."—ED.]

THE GAROTTERS.—Mr. Rolfe has just produced a card picture illustrating the *modus operandi* of garotting. The "nasty man," as the operating garotter is technically named in the "profession," is just putting on the hug; while the "front stall," whose duty it is to secure the plunder, with one hand seizes the victim's watch and aims a blow with a bludgeon held in his other hand. The background is too light, and does not represent night, but the action is very well managed. The illustration is a little late in the market: with returning spring the public have almost forgotten that garotters exist.

Talk in the Studio.

DOUBLE SULPHATE OF IRON AND AMMONIA.—This double salt recently recommended by M. Meynier as a developer in preference to the ordinary protosulphate of iron has been manufactured by Messrs. Horne and Thornthwaite. We find on trial that it has certain advantages. Using a 25-grain solution with 25 minims of acetic acid it gave very good results. The action was very regular and perfectly under control, giving greater density and clearer shadows than a similar solution of the usual protosulphate. This is what we anticipated, as the general presence of a large portion of sulphuric acid in the common protosulphate of iron tends to the production of a thin grey image, with slightly veiled shadows, and this in the double salt is avoided. M. Davanne expresses a conviction that with this latter the molecules are thrown down in a much finer state of subdivision than with the ordinary developer, thus securing a more delicate image. The double salt is also more stable, having less tendency to peroxidation.

PAISLEY PHOTOGRAPHIC SOCIETY.—We are glad to see from a local paper that a photographic society is in active operation in Paisley. A meeting was held on Thursday evening week, Mr. Robert Harris, Vice President, in the chair. The subject of the evening was recent improvements in toning processes. Amongst other things exhibited was a very beautiful print, taken from a negative photographed by Mr. Edmonds, from Mr. Stewart's fine painting of "Interrupted Studies," at present in the Edinburgh Exhibition, and Mr. Archibald Barr also exhibited some fine prints on the newly introduced tinted paper. Mr. John Clark, Gateside, presented to the society's library a handsome bound volume of the PHOTOGRAPHIC NEWS for 1862, in consideration of which, and also of the many valuable donations he has repeatedly presented to the society, they awarded him a cordial vote of thanks, and instructed the Secretary to transmit him the same. A vote of thanks to the Chairman terminated the proceedings.

AMMONIA DEVELOPMENT.—Speaking of the ammonia development, Major Russell says:—"In certainty, this method, as I now manage it, leaves nothing to be desired, and there seems to be less liability to stains, or spots, than in the acid method. The only points which I have lately found out are, that commercial carbonate of ammonia is a little better than the solution of ammonia, and that the best proportion is 1 grain to 1½ grain of the carbonate to 1 grain of pyrogallie, to be used in from 2 drachms to 1 ounce of mixed developer. Within these limits there is little difference in the effect; the stronger the developer the quicker its action, but the weaker the more entirely free from all veiling will be the negative: the amount of detail brought out does not seem to be affected by the degree of dilution within the limits mentioned. The best way is to pour the ammonia, dissolved in equal parts of alcohol and water, over the dry plate, then to mix the pyrogallie, and pour on again." A new edition of Major Russell's little work, "On the Tannin Process," will shortly be published. We have just received an interesting letter from Mr. Leahy, on the development of dry plates, in which he says lime-water will develop tannin negatives. The letter in our next.

To Correspondents.

A. LEWIS.—Your "spirit photograph" is much more spiritual looking than the alleged genuine pictures produced in America, which are very clumsily managed. The ghostly effect in your attempt is very well managed.

BROMIDE.—The arrangement of canopy or screens in taking portraits in the open air must depend largely on circumstances. The canopy may be made of the slate-coloured glazed calico to which you refer; the extent to which it should project forward over the head must depend much upon its height or distance above the head. The light should reach the head at about an angle of 45°, so that a canopy a yard and a half above the head should project about a yard and a half over it. There need not be a screen or wall on both sides necessarily; but if you have a wall on one side you will find a screen of three or four feet wide, and about as many feet from the sitter on the other side will help you to get softness, and prevent too much light falling quite on the side of the face. To prevent diffused light entering your lens, attach to it a large conical hood of cardboard blackened inside, and projecting about a foot, in size and shape something similar to a sugar loaf, but expanding a little more.

A MAN FROM THE COUNTRY.—The stain on the background of your negative appears to have arisen from an accumulation of the silver solution having drained to that spot, and become precipitated there by the developer. Try placing a strip of blotting paper along the bottom of the plate, which will absorb any surplus drawings. We have met with the tendency as you describe in a new bath, and there is something not explained in the circumstance that it should occur especially in a new bath; but we think you will find the remedy efficient. The general chemical quality of your negatives appears pretty good. Report on your glass in our next.

J. JONES.—We do not necessarily indorse or approve all the formulæ we publish, and amongst other things we do not recommend or practise ourselves, is the adding of alcohol to the nitrate bath. The ammonia nitrate bath with nitric acid added until it is neutral gives exceedingly good results. Let any turbidity subside, or if necessary, filter the solution.

ALPHA.—We think the lenses of the best English makers are decidedly preferable to the common French articles. The superiority consists in a variety of points, such as better definition throughout, greater rapidity, &c. We cannot, in fairness, recommend any maker by name. See our advertisement columns.

TOMPKINSON.—The *sel d'or* toning bath is a mixture of hyposulphite of soda and gold. Dissolve one grain of chloride of gold in an ounce of water; in another ounce of water dissolve three grains of hyposulphite of soda; now pour the gold solution in the hypo solution, agitating it during the process. Dilute with a couple of ounces of water, and when any turbidity or milkiness has subsided, filter, and it is ready for use. This process is now rarely used, as it has been abandoned for the alkaline gold process, which gives better and safer results.

G. H. M.—Fresh glasses generally need no other cleaning agent but alcohol and tripoli. Glasses that have been used should be cleaned with the same, with the addition of a little nitric acid; a little iodine may also be added with advantage; finishing with alcohol alone. If the plates are well cleaned, and the edges carefully rubbed to remove adhering particles, there is no danger of the bath suffering.

A. TANNER.—About four grains of the iodide of magnesia, and one or one and a half of bromide of magnesia, may be used with advantage in each ounce of collodion. It is desirable to evaporate the nitro-muriatic acid as closely as possible, without inducing decomposition, but it is necessary to be very careful towards the close of the operation, and work with a low temperature, or decomposition may suddenly take place.

J. B.—See article on "Glass Houses," in the present Number. A modification of Mr. Sutton's principle—getting a little more light—will probably suit you better than the design with top light only.

F. TABLE.—A combination of softness and delicacy with brilliancy is necessary to good results. In the earliest set, No. 1 is the most perfect negative, but it is not a good print, being too lightly printed. A little more printing would have given depth and richness to the drapery, and more roundness and modelling to the features. No. 2 is brilliant, but a little hard; a trifle more exposure, and less developing or intensifying, would have improved the picture. No. 3 is better in these respects; but it errs a little on the side of softness; it wants a little force. A medium between No. 2 and No. 3, or a combination of some of the qualities of both would give a fine result. If you examine the face of No. 2, you will find patches of white without any detail or drawing, which should never occur, and no richness or perfection of the drapery will compensate for this.

W. C. MARKET RASEN.—A longer immersion in the toning bath will give you deeper and blacker tones; but the highly albumenized *Rive* paper on which your print is produced is often difficult to get beyond the chestnut tone of your specimen, a tone which, however, many persons prefer. A few lessons from a capable instructor will be valuable; but we do not know anything of the qualifications of the gentleman to whom you refer.

ALEX. ARNHEIM.—Thank you for the samples of paper prepared with gutta-percha, we will take an early opportunity of trying it.

ONE WHO WANTS PRACTICE.—The print received is a specimen of imperfect fixation. The hyposulphite bath is too weak, or old and exhausted, or the prints have stuck together so that the solution did not act properly upon all. In this case the latter is probably the fact, as you state that some of the same batch were so and some perfect. The effect generally is first seen whilst the prints are washing. Prints perfectly washed before toning or after toning are much less liable to this mischance. There are no means of ascertaining when a print is fixed by its appearance. The only certainty can be obtained by taking care to observe all necessary precautions, such as careful washing, using fresh, strong, neutral hypo solution, keeping the prints in motion and free from sticking together, &c.

GEORGE DRAPER.—We did not find any print enclosed in your letter. Possibly a little alcohol will prevent the stains to which you refer; or possibly they may arise from the drainings of the plate; we tell from your description. 2. You may, without impropriety, defer intensifying until the close of the day, as is the custom with many artists. You may either allow the negatives to dry, or keep them in water just as you prefer; with the latter plan there is some chance at times of the film becoming loose.

F. L. S., EDGE HILL.—The chief fault of your pictures is the use of too much front light, giving the faces a uniform and flat effect, you want more distinctly marked light and shadow to give more relief.

A. WOOD.—We are obliged by the examples of the effect of steaming; which seem strikingly to prove its value. We shall look with interest for Mr. Nichol's paper on the subject. We should like to know something of your photolithographic process. We have not yet exposed the piece of excited paper, so that we shall learn something of its keeping powers.

A. BURNS.—The cards received; we will write shortly.

Y. Z.—Your sample of glass is very excellent, and may be used in the dark-room with perfect safety.

SKIES IN PHOTOGRAPHIC LANDSCAPES.

WHITE skies are no longer the "fashion" in photographic landscapes. A few years ago a photographic exhibition scarcely gave us examples of anything else in the shape of landscapes, but a foreground, surmounted by white paper in place of sky, or "buildings," to use the words of Lady Eastlake, "of rich tone, and elaborate detail, upon a glaring white background, without the slightest form or tint, like a Chinese landscape on a looking-glass." The "light having burnt out all cloud-form in one blaze of light." That which originated in a defect soon became a fashion, and the speckless sky, without the suspicion of a tint, was regarded as the pride of the picture. In the last Photographic Exhibition white skies were the exception; natural clouds, or graduated tints, were everywhere present. It is unnecessary here to dwell upon the immense pictorial value thus conferred upon each subject. A white patch of paper destroyed all brilliancy by killing all the lights in the picture. It destroyed all atmosphere by killing the delicate tints of the distance, and making that which should be afar off—the sky—the most prominent and staring part of the picture. It destroyed all breadth by cutting the picture into two distinct patches of light and dark, without harmony or connection. As a higher appreciation has been growing amongst photographers, a few words on the various modes of producing skies may not be uninteresting.

There are at least half a dozen modes in which skies are produced in photographs. The first and most obvious is that which is least under control, being possible only under certain conditions, namely, the production of clouds at the same time as the foreground, as in instantaneous photography. The second is by contriving during development to bring out the forms of clouds present during exposure, and to avoid over-intensifying them to that condition in which they never print through. The third is by managing to give the sky a minimum exposure while the foreground receives its full time. The fourth is by printing in clouds from a separate negative. The fifth is by painting or otherwise working on the negative. And the last is by exposing the sky to light after the print has left the pressure frame, so as to secure a graduated tint.

On the method of obtaining clouds by rapid or instantaneous exposures, we need not say much here. A cloudy sky surmounting a well illuminated foreground, containing no very dark objects very near to the camera; a highly bromized collodion and iron development, together with skill and judgment in selecting subjects and manipulating, are the chief requisites here.

Management in developing gives, under some circumstances, great power over the sky to the skilful operator. In some large pictures we have recently seen, by Mr. R. Gordon, of the Isle of Wight, of which we shall have more to say shortly, very good natural clouds were secured in negatives requiring eight or ten seconds' exposure. It will be assumed at once that the clouds in such instances had

not been in very rapid motion. This is a circumstance which not unfrequently occurs; but it in general happens, that in developing in the usual manner, the clouds which come out rapidly in development as rapidly disappear in one uniform mass of intensity, being buried by the amount of development necessary to bring out the foreground. To meet this difficulty, Mr. Gordon adopts a very ingenious method. Instead of applying the developer in its ordinary strength, he uses a one-grain solution of iron without any acid whatever. This, in a few seconds, brings out the delicate cloud forms, when there are any present, and to some extent the foreground. When its operation has been carried sufficiently far, the developer, which contains also the free nitrate, is poured off the plate, and a portion of fresh iron solution and acetic acid added to it sufficient to make a developer of the ordinary strength, suitable for the collodion in use. Mr. Gordon generally uses a similar solution to that of Mr. Vernon Heath, namely, 8 grains of iron and 20 minims of acetic acid. This solution is now applied to the plate, confining it chiefly, but not exclusively, to the foreground. The whole of the detail sufficiently out, sufficient intensity is secured by a two-grain solution of pyrogallie acid and a few drops of silver. By this means a negative is obtained, in which the cloud-forms are not buried in one mass of intensity, but print sufficiently to give harmony and atmosphere to the picture. It will be seen that this method is analogous to that used by Mr. Mudd, with dry plates, in which a plain solution of pyrogallie acid is applied until the clouds and general details appear; the ordinary pyrogallie solution, with citric acid and silver being then applied to give intensity to the foreground.

Various contrivances have been tried for protecting the sky whilst the foreground received its proper amount of exposure. Mr. Scott Archer had a plan of tearing a piece of paper to a form corresponding with the horizon line in the view to be depicted, and placing it inside the camera in a groove, so that it cut off the sky during part of the exposure, when it was removed to give the sky a few seconds only. The flap shutter placed before the lens has frequently been used to partially shade the sky; but this is only available when no tree, spire, or other object materially breaks the level of the horizon. Mr. Mann has recently patented a shutter, which it is stated can be made to adapt itself to any line dividing the sky and landscape, however irregular, and thus give absolute control over the respective exposures for each part.

The method of printing-in a sky from a separate negative is pretty well known. Mr. Samuel Fry was, if we remember rightly, one of the first to call attention to the advantages of this method, which he described in our pages some time ago, when its legitimacy was the subject of considerable discussion. It was alleged against this plan, that to secure truth and harmony, the landscape should only be accompanied by the same sky which was over it at the time when the picture was taken. It was argued, on the other

hand, that the portion of the sky seen by the lens was not necessarily that which, by the reflections of clouds, &c., affected the portion of the foreground seen by the lens, and that if care and judgment were used in selecting the sky for each subject, harmony might easily be secured. This plan has been gradually gaining popularity, and is now practised by many of our best photographers, amongst whom we may name Mr. Vernon Heath, Mr. Maxwell Lyte, Mr. Annan, Mr. Archibald Burns, and others. Two or three points demand imperative consideration. The clouds must be lighted in a similar manner to the landscape, and must be of a character to harmonize with it. Nothing would be more incongruous than heavy dark masses of cloud in the sky, when the landscape, perhaps, presents a lake which reflects only bright sunlight. Care must always be taken that the sky be lighter, more atmospheric, and less substantial looking than the foreground. As a general principle, the more light, indefinite, and less pronounced the clouds, the better will be the effect. It is scarcely necessary to say that in using this method immense power is placed in the hands of the artist in balancing his composition, and making a picture out of unpromising materials.

The method of painting on the negative has been often attempted, but rarely with complete success. Indeed it can scarcely be expected that it should be successful in other than the hands of an artist. The Eastern pictures of Mr. Francis Bedford afford the best example of successful treatment of this kind that we have seen, and the effect is marvellously fine. It is a necessary condition in this case that the sky of the negative be not too dense; it must print through, giving an appreciable tint. The clouds may then be carefully painted at the back of the negative; or they may be painted on thin semi-transparent paper like tracing paper, which can then be placed at the back of the negative. The safest plan is that adopted by Mr. Mudd who contents himself with a few delicate stratus-like clouds near the horizon, which are just sufficient to break the blank of white paper, and give some gradation.

The simplest plan of avoiding a mass of white paper for a sky consists in giving graduated tint by exposing the print, after it has left the pressure-frame, to the partial action of light. This, if done with care and taste, preserving light in the horizon and running into a darker tint higher up, avoiding at all times too deep a tint, or one in any degree as heavy as the shadows of foreground objects, is often very successful and satisfactory, and can very rarely be offensive.

We do not here enter into the question of the legitimacy of any of these methods of giving pictorial value to the photographic landscape beyond reiterating a conviction we have often expressed, namely, that in such matters success is the touchstone of legitimacy.

Critical Notices.

INSTANTANEOUS AND OTHER STEREOGRAPHS.

By G. W. WILSON, Aberdeen.

WE have recently received a further series of Mr. Wilson's exquisite instantaneous and other stereographs, amongst which we find some of the most perfect photographs we have seen. The instantaneous pictures are wonderfully fine and full of life and motion: three of the Thames at Greenwich—"Waiting for the Boat," "Arrival of the Boat," and "Departure of the Boat"—are excellent examples. The crowded pier; the transparent water; the forests of masts which form the distance in which looms heavily, with tier upon tier of decks, the noble hospital ship; the fine clouds all combine to make most picturesque views. "The Thames at Woolwich" (No. 418) is another exquisite slide, low in tone, but wonderfully delicate, detailed, and soft, and a most admirable example of composition. The "Victory Flag Ship, at Portsmouth," is another fine slide, as brilliant as the other is soft.

There are many more of the instantaneous pictures of marine subjects which are very fine; but the slides in this series which please us most are the views of Highland scenery, which far exceed any views of the same or similar subjects we have seen. Here is a series of Loch Katrine, which is inexpressibly beautiful, so perfectly chosen as regards point of view, so brilliant and delicate, so full of gradation, from the tender greys of the distance to the forcible and bold relief of the foreground and the transparent depths of the water. No. 10 B, "Loch Katrine and Ben Venue," is an admirable example of this series, as is also "Ellen's Isle" (No. 36), the sparkling little lights of which more resemble the work of the engraver than the lens. "Loch-na-gar, Balmoral," is another noble slide of the same series.

A series of interiors and exteriors of English cathedrals includes some exceedingly fine pictures, amongst which we like those of Durham best. A view of the cathedral from the river Wear (No. 380), is exceedingly beautiful. The interior of the "Galilee, or Lady Chapel," in Durham Cathedral, is very fine, and renders very perfectly the fine examples of Norman arches. No. 407, the "Lady Chapel" interior, in Winchester Cathedral, is an exceedingly fine study of lighting and perfect chiaroscuro. Amongst some other very fine interiors, perfect in lighting and manipulation, it is to be regretted that there is not an entire absence of curved, or converging, perpendiculars. With this exception, in a few instances, the whole of the pictures before are perfect examples of art-photography, forming not only some of the most pleasing slides ever issued to the public, but containing most valuable studies for young photographers to adopt as standards of excellence to which they should try to attain.

INSTANTANEOUS VIEWS OF LONDON. &c.

By VALENTINE BLANCHARD. London: C. E. Elliott, Aldermanbury Postern.

WE have here a further series of Mr. Blanchard's instantaneous views of London streets, and marine and river scenery, of which we have repeatedly had occasion to speak in very high terms. The slides before us include some of the most interesting, and, at the same time, most difficult street scenes in the metropolis, the difficulties here being increased by including vehicles, on a large scale, in the immediate foreground. We have not space for a detailed notice of each slide deserving notice; but we may mention as amongst the street scenes, which please us best, "Regent Circus, Piccadilly" (No. 204), which is a very charming soft picture, with natural clouds, falling exactly in the right position for balancing the composition; "London Bridge," from Southwark (No. 220), is also a fine slide. The marine and river scenes are our favourites, and these include many charmingly artistic bits. Here is "The Thames at Richmond" (No. 228), somewhat low in tone, but a most charming little picture, with a fine sky; it includes the bridge, boats, &c. No. 235, a "Study at Tilbury," of an old paddle steamer laid high and dry upon the strand, is also very fine. No. 240, "Gravesend from Tilbury," is another very artistic view. We might easily go on selecting choice specimens, but we must forbear, simply heartily commending the series to the attention of lovers of artistic photography.

RAMBLES ABOUT CHESHIRE. Photographed for the stereoscope, by J. H. UNDERWOOD.

THIS is a continuation of a series we have before had pleasure in noticing and commending. It includes some very pleasant bits of rural scenery, very perfectly photographed: great brilliancy, combined with detail and softness characterise all the pictures.

VIEWS IN NORTH WALES. Photographed by JACKSON Brothers, Junbo and Oldham.

NEARLY a couple of years ago we reviewed a series of photo-

graphs, chiefly consisting of rural studies and landscapes with figures, by Messrs. Jackson Brothers, which struck us at the time as unusually picturesque and artistic. We have here a series of views in North Wales, which, whilst different in character, consisting of natural scenery rather than artistic studies, are selected and executed with equal artistic feeling, with one slight drawback, however, namely, that in some instances we have white skies. In all other respects this is one of the best series of photographs of Welsh scenery we have met with.

TRAITE GENERAL DE PHOTOGRAPHIE, Comprenant tous les Procédes connus jusqu'à ce jour. Par D. V. MONCKHOVEN, Quaterième Edition, Paris: Victor Masson et Fils.

The fourth edition of Dr. Van Monckhoven's *Traité Général* has been entirely re-written, and is, perhaps, the most complete work on photography in existence, treating most fully alike of the theory, practice, and scientific applications of photography, and being illustrated with upwards of two hundred and fifty engravings. We heartily commend it as a work which should be in the library of every photographer who reads the French language. Dr. Monckhoven is not only a careful and conscientious compiler, but himself a man of high scientific attainments, and a high authority in the chemistry of photography.

REPertoire ENCYCLOPEDIQUE DE PHOTOGRAPHIE. Par H. de la BLANCHERE. Tome I. et II. Paris: 39 Boulevard de Capucines.

This is another very comprehensive French work of reference on the art of photography, and professes to comprise, in alphabetical order, all which has been published in France and other countries since the discovery of Daguerre and Niepce on the art of printing by means of light, and of chemistry, physics, and art, so far as they relate thereto. The alphabetical treatment of all matters photographic is completed in two closely-printed 8vo. volumes; but to keep pace with the progress of the art, the work is continued in monthly parts, which recommence the alphabet, and proceed to include the progress of the art to the latest possible period. The work displays great research and care, and is invaluable as a work of reference on the history, theory, practice, and applications of the art.

TRAITE DE L'IMPRESSON PHOTOGRAPHIQUE SAN SELS D'ARGENT. Par ALPHONSE POITEVIN, avec une Introduction par M. Ernest Lacan. Paris: Lieber

A most interesting history of the origin and progress of the various methods of obtaining photographic impressions without the salts of silver, whether by carbon, photolithography, or photographic engraving. To all photographers interested in this branch of the art, so important in an economic point of view, this brochure will be most welcome, both as recording the history and describing the methods of operation. The value of the work is most materially enhanced by illustrations, produced by the various processes described, including a carbon print, containing very perfect half-tone. The book is manifestly the work of one with whom the art, to the progress of which he has contributed so much, has been a most all-absorbing passion. We notice in some cases, that he has fallen into some inexactitude in dates, but there is a manifest desire to perform the work in careful and conscientious spirit, and we commend it very heartily for its practical value.

AN EXPERIENCE WITH THE OLD HYPO BATH.

BY CARL MEINERTH.

[WE have received from Mr. Carl Meinertth of Portsmouth, New Hampshire, U.S., a series of prints, in illustration of an article in the *American Journal*, to which he calls our

attention, and which we here subjoin. The prints include some exceedingly fine specimens of photography, and are very perfect in tone. The colours vary from a deep rich warm neutral tint to a deep black, and, notwithstanding their long immersion in the old hypo bath described, they have not the faintest indication of the yellow tint we generally find accompanying the blacks so produced, and which so oft-n indicates incipient decay. The prints are card vignettes, presenting therefore, a large surface of white, which is exquisitely fine. So far as there is present indication, the tones are good, and with every promise of permanency. How far that promise will be fulfilled, time alone can decide. In the mean time, we are bound to add that the alkaline gold process is, we think, the most trustworthy method we at present possess.—Ed. P.N.]

When a vicious boy changes his mind, repents his sins, and by degrees in his later days becomes a good man of estimable character and qualities, we ought not surely to condemn him for ever for his juvenile sin. Would that we could say so with some hope of the old boy, Hypo, whose pranks made him so odious with us, that he was despised and turned out years ago, with disgrace, so much so that we now feel almost ashamed even in mentioning his name; and one must fear to be considered a candidate for some certain asylum, if he dares undertaking to restore him to society. Yet who of us would not be willing to welcome him back to homo and hearth if he could and would give up his rank habits and unstable qualities, for the slow but lasting virtues of his younger golden brother, Alkaline?—the "gold-solin'chen," as the Germaus would call him.

But let me report an accidental case of experience with the boy, which induced me to extemporise in these charitable mediations in his behalf:—

In May, or June of last year, I prepared a "rich toning and fixing bath," for experiment, and for quick work (as for any other I have used none but the alkaline), which as usual produced very fine tones, but the whites turned yellow after a few days, and even as soon as the prints were dry; now, these yellows even in pictures of no intended value or durability, can, to use a vulgar phrase, make any one mad! Well; so after they appeared, young master Hypo, after this first exploit of yellowizing that batch of prints, was corked up, and put into the dark closet, until I could treat him to a dose of ferri sulphas, to disgorge the gold from his pockets, in order to prevent further mischief by temptation. But this was never executed, and he was left in statu quo until about two weeks ago—thus eight months.

Gathering up, as I said, about two weeks ago, old bottles and solutions, I came across the old offender, and as it were, wishing to give him the last chance for repentance, poured him out into a dish and threw a handful of over-printed, unwashed albumen prints into it. This was in the afternoon; other business made me neglect these prints entirely, until the next morning, when to my surprise I found them beautifully white or black, and the solution perfectly clear. I soaked the prints for only about an hour in one water, still suspiciously expecting that they would turn yellow after drying; but they did not, and have so far not shown any symptoms of the yellow fever, and also look not likely as if they would [I enclose a few of those original prints, and beg for your opinion, Mr. Editor, of their toning quality, and for preserving them, and reporting on their stability at some future day.]

Now to sum up: this bath was eight months old; the prints were left in it eighteen hours, and received only one hour's soaking afterwards.

The tone of them is, in my humble opinion, —; (but let the Editor speak), and the white of the vignette is as pure as the edge of the surrounding card.

When this same bath is freshly prepared, prints toned in it in thirty minutes and washed very carefully in warm, and then in running water for four hours, go to "lemons" very soon, if not already while drying. But I must mention the composition of the bath:—

Water	16 ozs.
Hypo	8 ozs.
Sal ammoniac	2 ozs.
Nitrate of silver	40 grs.
Gold...	15 grs.

The result of the present experiment seems to indicate that

age is the agent which produces in the hyposulphite bath, as in LeGray's, and in fact in a great many chemical combinations or mixtures, an important and most favourable change. It seems to lose its rank "yellowizing" quality, so that even an excessively prolonged time of toning and fixing will not injure the albumen print, nor the middle-tints of the picture.

As the old rule is, in order to obtain the best possible results, to prepare the bath fresh every time, to tone and fix as quickly as possible, and to wash as much as possible; yet the experiment above was made under exactly the reversed conditions, and has produced a very superior result.

However, at the first glance, we may ridicule the idea, that such a bath which requires half a year waiting, and a whole day toning, should be worthy of any consideration in view of exchange for the trouble of washing, with the alkaline bath, even if the photographs toned therein should really prove equal in keeping with those toned in the latter. Yet an amateur, as well as "operator," will, after a little reflection, agree that such a bath, even if not preferable, is not undesirable; and consequently a step towards its perfection not so much out of the way. We must perceive, of course, that neither "eight months" nor "eighteen hours" are requisite for obtaining good results, as that amount of time was merely accidental. I have since got very fine tones in half an hour's toning in the same bath, whereof I also enclose a specimen. As to the *age* of the bath, it is probable that it may work as well after four weeks as after as many months: which fact further practical experiments alone can prove.

ON SOME NEW PRINCIPLES OF DIRECT PHOTOGRAPHIC PRINTING ON PAPER.

BY M. POITEVIN.

In the new principles of permanent printing in carbon or other inert pigment, which I submit to the Photographie Society, the pigment remains, as I proposed in 1855, imprisoned in an organic material, originally insoluble, and remaining so in those portions not acted upon by light, or coagulated in certain parts only of the impressed surface. I append some proofs to my description, for which I crave much indulgence: accustomed as we now are to see only perfect photographs obtained by processes arrived at the highest degree of perfection, it is an act of temerity to exhibit imperfect specimens obtained from immature processes. In these experiments I have had everything to do under the worst possible conditions; first, from bad weather, for these new experiments only date from November last; then the study of the materials and their proportions, the particular quality of the paper, as well as of the negatives inappropriate to this kind of printing. However, if these first proofs do not militate in favour of the process, we may judge by the description of the principles, what we may be able to obtain hereafter with great facility and at little expense, as we operate directly upon the paper, the use of collodion for transfers, indispensable in my former processes, being now surpassed.

The first principle, that which I have most followed up to the present time, rests upon a well known reaction—the insolubility communicated to organic matters, such as gum, albumen, gelatine, &c., by *maximum* and analogous salts of iron, the perchloride, for example, and upon a new fact which I have observed, which is, that this matter coagulated and rendered insoluble in cold or warm water, becomes soluble under the influence of light, in presence of tartaric acid, which reducing the ferric compound, restores the organic matter to its natural state. Gelatine is the substance with which I have succeeded best. The following is my mode of operating.

I dissolve 5 to 6 grammes of gelatine in 100 grammes of water, and add sufficient quantity of carbon or other inert pigment to obtain the intensity of tone I desire to produce. I pour this solution into a flat dish, and keep it warm so as to prevent the gelatine solidifying. Each sheet of paper is floated on one side only on this solution, and a uniform coat of coloured gelatine adheres to it; I then place the sheet of paper on a flat surface and leave it to dry spontaneously.

To sensitize these sheets, I impregnate them on both sides with a solution of perchloride of iron and tartaric acid in the proportion of 3 to 1. The quantities which have appeared to me most suitable being 10 grammes of perchloride to 100 cubic centimetres of water, and 3 grammes of tartaric acid. I leave the sheets thus prepared to dry in the dark; then the coating of gelatine has become completely insoluble, even in boiling water. I print these surfaces from positives on glass or on paper, and in all those portions upon which the light acts, the coating becomes soluble in warm water; this solubility, be it understood, commencing from the surface. After a few minutes' exposure to the sun, if the positive *cliché* be not very dense, which is preferable for this kind of printing, I remove the paper from the printing frame, and immerse it in warm water; thereupon all the parts which have been modified by light dissolve in proportion to the quantity of light which may have passed through the various portions of the positive *cliché*. In the parts corresponding to the lights of the *cliché*, the black or colored coating will be dissolved down to the surface of the paper, leaving perfect whites, while in the half-tones a part only of the coating will dissolve, commencing with the surface, and these half-tones will be rendered upon the greater or lesser thickness of the coating of gelatine remaining insoluble; and as this part is in immediate contact with the paper, it cannot be removed by washing: as to the portions of the negative which are entirely black, they will be rendered by the entire thickness of the primitive coating.

To complete the proof, it is only necessary to dry it in the air, or treat it with water acidulated with hydrochloric acid, which removes the stain of salt of iron, then to wash it freely in water, and dry it again spontaneously. It is now unchangeable, but a tanning of the gelatine, accomplished by known methods, with alum. bichloride of mercury, &c., will give it greater solidity. Before this fixing we can make whites wherever they may be required, by means of a pencil dipped in warm water.

We do not encounter such dangers in this method as presented themselves in that I proposed in 1855, in which I employed a coating of gelatine mixed with an alkaline bichromate and carbon, and which I printed by means of negatives: for in that method the gelatine was rendered insoluble by light, commencing at the surface, and the half-tones were removed in the washing, undermined from beneath by a portion of the coating remaining soluble. The method I now propose does not possess this inconvenience, and to obtain perfect proofs by it requires only suitable paper with a glazed surface, uniformly coated with a film of the coloured preparation, which will be found easy to realize in practice. The proofs I now present have not been obtained under these favourable conditions, and must therefore be considered only as the products of a new reaction, and the *débuts* of a process.

As to the second principle, it is only a new application of a known reaction, the coagulation of an organic substance in solution by a salt of iron or by a vegetable acid. It consists as follows:—The paper, impregnated with perchloride of iron and tartaric acid dissolved in the proportions indicated in my mode of printing on glass, having been exposed to the light through a positive *cliché*, obtains the property in all the parts which have not been acted upon by light, of precipitating caseine (e. g., of milk) in solution on its surface. I therefore mix the pigment in powder with a solution of caseine, alumina, &c., and I immerse the impressed paper in it, and a layer more or less thick is formed upon the portions not solarized proportionably to the half and whole tones of the *cliché*; if we replace the caseine by gelatine, the latter goes to the solarized portions. In either case the organic matter carries with it a certain quantity of colouring material, holds it imprisoned, and forms the picture. I shall again recur to this reaction, so easy to practice, and exhibit proofs so obtained.—*Bulletin de la Société Française de la Photographie.*

EXPEDITIOUS METHOD FOR THE COMPARISON OF PHOTOGRAPHIC SUBSTANCES.

BY M. MC. A. GAUDIN.

In order to be able to make the numerous trials I have undertaken in that branch of photography which relates to the employment of collodion for the formation of images in the camera-obscura, I contrived a process at the same time comparative and expeditious, of which I have spoken before, and now proceed to describe in full, being persuaded that it will be found useful to photographers on many occasions.

At the present day the main thing is sensitiveness, and that has been the steady aim of all my efforts for more than twenty years. Notwithstanding the multiplicity of my attempts, of which no one can form any idea, I have discovered very little; but this has not discouraged me, and in any case this process will be very useful in practice, if it does not become fruitful in inventions in the hands of every body.

Success in photography depends particularly upon the mutual accord existing between the collodion, the silver bath, and the developing agent, which is fully realized only in taking proofs; but to appreciate the sensitiveness the question becomes complicated with that of the intensity of the light, and the focal distance of the objective and its diaphragm, the time of exposure, the nature of the object, and the intensity of the image obtained: so that, the operation concluded, we find ourselves greatly embarrassed to decide the principal question started, namely, the sensibility. While, with the process I now proceed to describe, we can, at all times, by night as well as by day, prove the effective sensitiveness of its products on the relative sensitiveness of two collodions, with great promptitude, and without any apparatus.

We employ plates of glass eight inches long and two inches wide, which, by their elongated form, permit of our operating upon a small scale without the contact of the fingers or frames, which is often the cause of the proofs becoming fogged. After pouring the collodion upon the extremity of the plate, so as to cover a space of two inches square, we immerse this extremity, collodion downwards, into the dish containing the silver solution, the other extremity resting upon the edge of the dish, which must be covered with a piece of card-board. After sensitizing, we place upon the back of the plate a piece of moistened yellow paper, cut square or triangular, which adheres, and we then present this paper to the flame of a candle, at the distance of four inches, counting seconds from 0, 1, 2, 3 to 9, removing the paper between 9 and 10. By this means we have, side by side, two exposures; the one of ten seconds, the other of one only, which, after the application of the reducing agent, will mark, if the sensitiveness is at the maximum, the one, an intense black, the other, sensibly of a half tint; but if the sensitiveness is weak, the exposure of ten seconds only will be marked.

We at once understand that this manner of operating gives results always comparable at any season, and at any hour of the day and night. If the developer is susceptible of fogging, it will show itself after the washing with hyposulphite of soda, the space left masked in the last place by the screen of yellow paper will not appear perfectly black upon a black ground, provided, however, that it be held three feet from the candle during development.

To compare the sensitiveness of two collodions is also very easy: we pour on the extremity of the glass plate a film of each collodion, thus forming two contiguous squares, which are sensitized together; and after placing at the back a slip of yellow paper across the line of separation of the two collodions, and impressing these collodions by the light of a candle as before described, upon the application of the developing agent, we may clearly ascertain which is the most sensitive of the two collodions.

With 150 grains of collodion we can make twenty trials in an hour. It is by following this method that I have

recently made numerous experiments upon the introduction of iodide of silver, protochloride of tin, and the iodides of iron, tin, and antimony into the collodion.

Iodide of Silver in Collodion.—The introduction of iodide of silver into collodion appears to me a good way of increasing the porosity of collodion and augmenting its sensitiveness. This idea is not a new one, as the first collodions prepared contained iodide of silver, but theoretic notions have caused this accessory to fall into disuse. Still, it is quite certain, that when iodide of silver exists in collodion at the same time with iodide of potassium, we need not fear that the iodide of silver will be impressed by light, since, on the contrary, if it were impressed in advance, in the highest degree, the contact with iodide of potassium would restore it to its original state. During my long researches upon the *photogène* for collodion, I have been led to believe that most of the iodides act upon iodide of silver, like the iodide of potassium, but in a much less degree. This is why I have introduced some iodide of silver into a collodion iodized with iodide of cadmium, working well, and I have left the bottle exposed to sunshine for half an hour. When I afterwards coated my slip of glass impressed by the flame of a candle, I obtained as pure an image as ordinary. I have, therefore, concluded that iodide of silver, with excess of iodide of cadmium, is *insensible* to light, and that we may carry the addition of iodide of silver to collodion very far. Only the great difficulty is in obtaining it in the collodion in the nascent state, and not in the state of suspension: in the nascent state, the collodion is opaline, just like a sensitized film, and the iodide is never precipitated, while, if in a state of suspension, it very quickly subsides to the bottom of the bottle if left to repose. This difference in the behaviour of iodide of silver declares itself at once under very different circumstances: for example,—to prepare collodion with opaline iodide of silver, it is better first to introduce into simple collodion a drop or two of a concentrated solution of nitrate of silver, then to add the alkaline, or metallic iodide, in the usual proportion, and shake the bottle until the whole is dissolved. By adding nitrate of silver to collodion already iodized, the collodion almost always *turns*, and the iodide very quickly separates upon standing, with the exception of a very minimum portion, which is incapable of producing the least useful effect.

Protochloride of Tin in Collodion.—The protochloride of tin, introduced in a *very minute* quantity into collodion, iodized or not, produces an extraordinary effect—fully comparable to that of gallic acid: after sensitizing, the film has assumed a light-brown hue, which is not modified by the action of light; so that a plate thus prepared and exposed yields no image, but under the action of the reducing agents its whole surface assumes a uniform red hue of extraordinary intensity. The addition of free iodine to this collodion ultimately gives sensitive plates, so that protochloride of tin produces the opposite effect to free iodine; and in the present case it may serve for this latter. A collodion become very red by old age will almost immediately recover its sensitiveness by the addition of a few drops of a collodion prepared in the ordinary proportions with protochloride of tin. The reason of this phenomenon is very simple: the protochloride of tin, in presence of nitrate of silver, forms chloride of silver and nitrate of per-oxide of tin, which immediately gives rise to the formation of deutoxide of tin, which causes the reduction of the silver. Protochloride of tin is already known for reducing the salts of gold, and its reaction is still more marked with nitrate of silver: it takes place instantly, which prevents its employment for developing photographic images.

Preservation of the Ferroso-Acetate.—The preservation of the ferroso-acetate being a condition of primary importance, for its employment as a developer in photography, I have tested it under this relation. I left a pint of a weak solution of it in a wide-necked bottle, uncorked, exposed to the atmosphere for three weeks, using a portion every day, without observing any diminution in its power of reduction,

which proves to me, that, preserved in a concentrated state in a corked bottle, it will keep for an indefinite period of time. It is a bright red liquid, but the iron is not in the state of peroxyde, for ammonia precipitates it green, like all the developers with an iron base, employed to develop negatives. —*La Lumière.*

A SIMPLE METHOD OF CHOOSING GLASS SUITED FOR THE OPERATING ROOM.

The following letter from Mr. England was read at a recent meeting of the Photographic Society:—

DEAR SIR,—Having seen several inquiries lately respecting the coloured glass best adapted for the operating chamber, I am induced to offer a few suggestions, which, in practice, will be found to save much trouble and many failures.

On my visit to several photographic studios, it has surprised me the small amount of light, or rather the large amount of darkness, in which the plates are prepared, developed, &c. Now, by a little care in the choice of proper glass, we may have a window containing as many superficial feet as at present inches, thereby working with much greater freedom, comfort, and certainty, instead of fumbling about in the dark, upsetting solutions, breaking bottles, and losing your—no! I ask pardon, a photographer never loses his temper; a more patient race of mortals has not existed since the days of Job; and should some future Foley or Bailey choose as a subject for sculpture that worthy patriarch, he will, without doubt, wend his way to the nearest "Temple of the Sun" for his model.

But to proceed. Procure from a glass-cutter several pieces of coloured glass, say two inches square; number these, and place them in a pressure-frame, cover with a piece of sensitive paper, and expose to strong light till printed. The results will show at a glance the tint best adapted to stay the passage of the actinic rays. It will then be as well to try the same experiment with a collodion plate, to ensure perfect results.

One of the prints sent has had an exposure of four hours in strong sunshine, and still No. 1 square has received but very slight change. The second print has been exposed a shorter time, and exhibits in a perfect manner the various tints.

The accompanying prints and glass will fully explain themselves.

To the grandmothers of photography, of course, this is but pap; but to amateur infants, perhaps, a little of that article may be acceptable, and which must be my apology for troubling you.

W. ENGLAND.

7, St. James's Square, 3rd Feb., 1863.*

THEORY OF POSITIVE PRINTING.—ALBUMENISED PAPER AND THE ACTION OF THE SENSITIZING BATH.*

BY GEORGE PRICE.

THAT I may not be considered presumptuous, or actuated by motives of vanity, in addressing those who are much more practically conversant with every branch of photography than I am myself, allow me to assure you that I should not have come thus prominently forward had I not been solicited to write a paper for one of our meetings. I have complied with that request, because I consider that every one who becomes a member of our society virtually binds himself to do all in his power to aid the others in their endeavour to acquire knowledge, however humble may be his own abilities; for, though by reading a paper he may not himself be able to impart any information, or even to place his subject in a new point of view, he may, perchance, give rise to a discussion in which many important facts may be elicited.

The subject which was proposed to me was PRINTING; and it is, without doubt, the most important branch of the art, inasmuch as, without it, the others would be comparatively useless, for we should be unable to disseminate throughout the world the beautiful results which photography is capable of producing.

Although we are able to produce splendid prints by very different formulæ, still, it is an undeniable fact, that we absolutely know nothing whatever respecting the theory of positive printing upon albumenized paper; even the philosophy of the action of the preliminary sensitizing bath is but little understood; and

thus many erroneous notions are prevalent respecting it. Notwithstanding I am not conceited enough to imagine that I know any more of the subject than yourselves, it is nevertheless the one to which I invite your attention in order to raise a discussion upon a few points that require elucidation, believing that the illumination of even a farthing insight is preferable to total darkness.

Unfortunately for the progress of science, the majority of mankind have no individual opinions of their own, but accept those of others, without caring to take the trouble of ascertaining whether the opinions they adopt are facts or fallacies. It is, I believe, this universal acceptance of several fallacies as facts, that has so much retarded the advancement of our knowledge respecting the philosophy of positive printing upon albumenized paper. A fallacy is like the fabled *hydra*; if you cut off one head, another springs up to supply its place; and like *slender*, it lives long and travels far and wide. Should we flatter ourselves that we have killed it in England, lo! it makes its appearance in France; when we imagine we have destroyed it in France, we find it resuscitated in America; and when we hug ourselves with the idea that it is deprived of life in America, we are startled by its appearing again in England, enlivened with new life and vigour.

On a sheet of paper, which has been albumenized for photographic purposes, we have a superficial layer of dried albumen in conjunction with a salting chloride, this dried chlorided albumen being soluble in water. Notwithstanding I have written so much in the NEWS, endeavouring to expose the fallacy of the belief that dried albumen can be coagulated, it is necessary to say something about it here, not only in order to have a comprehensive view of our subject, but also in order to clear away much error which exists amongst photographers and scientific men respecting it. Any one who is conversant with the various branches of science must be aware that there is much looseness of expression in giving a name to various phenomena.

It is from this looseness of expression that so much error has arisen from using the word "coagulation." In making use of this term, we should bear in mind that it was originally given as a name for the phenomenon which takes place upon the application of heat to albumen in its normal state; and was intended to signify the production of a *semi-solid opaline mass*. As other agents were afterwards found to produce the same apparent effect, and insolubility was an invariable accompaniment, the expressions "insoluble albumen" and "coagulated albumen," came to be considered as synonymous when applied to the effect produced by these various agents upon normal albumen. Upon the erroneous supposition that what would render albumen insoluble when applied to it in its normal state, would also do so in its dried state—the term "coagulation" came to be mis-applied to dried albumen; losing sight of the important fact that fluidity of the substance to be coagulated is an absolute necessity. It happens, however, that several agents which will render albumen insoluble when applied to it in its normal state, will not do so when applied to it in its dried state; heat and alcohol are the only two of them which it is necessary to mention here.

Notwithstanding the assertions and opinions of many photographers and scientific men to the contrary, I unhesitatingly affirm that these agents (heat and alcohol) cannot render dried albumen insoluble; and, moreover, we have no means whatever of rendering it so; we may form an insoluble compound by chemical combination in various ways, but it is then no longer albumen; and whatever means we employ to do so before sensitizing, will, I believe, render it unfit for photographic printing. I think there can be very little doubt that the term coagulation, as synonymous with insolubility, was applied to dried albumen by photographers before it was recognised that it entered into chemical combination with nitrate of silver; but now, that such is known to be a fact, to say that nitrate of silver coagulates the dried albumen is erroneous in every way. In the first place, as there is no fluidity, there can be no coagulation (according to the original meaning of the term); in the second place, the expression cannot with any correctness imply that the dried albumen has been rendered insoluble, for it is the new chemical compound which has been formed that is insoluble (and to which has been given the name of albuminate of silver) and not the dried albumen *per se*.

The coagulation of albumen by heat, and its (so called) coagulation by chemical agents, are two separate and distinct phenomena; but photographers un-scientifically apply to them the

* Read at a meeting of the South London Photographic Society, March, 12th, 1863.

same term. In *what* way heat coagulates albumen chemists have not yet determined; but no *additional* substance enters into combination with it; it is simply the same albumen in another state; it is not so, however, when chemical agents are employed to produce insolubility; the *generality* of them enter into combination with it, and an insoluble *precipitate* is formed, which is not albumen alone, but a *compound substance*, and no one has any right to *mis-call* it *coagulated albumen*. I have said the *generality* of these chemical agents enter into combination with albumen, because I believe that alcohol simply unites with the water of the albumen, and causes an insoluble precipitate to be formed, with which it does not enter into combination; this may, perhaps, be the case with the coagulating *acids*, as it is not yet satisfactorily determined whether they form any definite compound with albumen; it is, however, otherwise with such metallic salts as nitrate of silver—here a direct chemical combination takes place. I have also said, *we have no means whatever of rendering dried albumen insoluble*; for I maintain that when normal albumen is coagulated by any agents, without their entering into chemical combination with it, those same agents, as they cannot *coagulate* dried albumen, *do not render it insoluble*, the insolubility of the normal albumen being due to its coagulation.

From what I have now stated I leave you to judge whether it be not want of knowledge which can alone induce any one to use the term *coagulation* in any way whatever when applied to dried albumen.

I need, perhaps, scarcely say to those who have paid any attention to the subject, that this fallacious notion of dried albumen being capable of coagulation, *even by heat*, is very prevalent, notwithstanding it is at variance with the dictates of common sense. In a pretty extensive and varied course of reading, I have never yet met with any author, be he photographer or chemist, who has ever stated the *impossibility* of so coagulating it; the most that any of them has advanced is, that it is not coagulated up to a certain temperature.

Mr. Hardwich, in the last edition of his *Manual of Photographic Chemistry*, leads his readers to suppose it to be a *possibility*. At page 470 he says:—"A layer of dried albumen cannot easily be coagulated by the mere application of heat." Now, we all know that when a person says a certain thing cannot *easily* be done, the inference to be drawn from his statement is, that it *can be done* with difficulty. Again, in speaking of albumenized paper, at page 371, he says:—"Some have recommended to press it with a heated iron, in order to coagulate the layer of albumen upon the surface; but this precaution is unnecessary, since the coagulation is perfectly effected by the nitrate of silver used in sensitizing; and it is doubtful whether a layer of *dry* albumen admits of coagulation by the simple application of a heated iron." You will, no doubt, have noticed that he does not say the application of the hot iron is *useless* for coagulation; but, merely, that it is *unnecessary*, because it will be effected by other means, thus ignoring the beneficial effect produced by its desiccating the paper; and you must be well aware that the statement, "*it is doubtful*" whether a thing can be done, is, in fact, an avowed acknowledgement that *it is not certain it cannot be done*.

M. Gaudin, in an article lately published,* alluding to albumenized paper, says that it will be sufficient to hang it in a cellar, or other damp locality, to coagulate the albumen by the passage of a hot iron across its surface; and also that at the time of albumenizing if the hot iron be passed over it before it is dry enough to cease sticking to the fingers, the same effect will be produced. Now, this statement is a *very great fallacy*, for the following reason:—Whatever moisture is imbibed will be evaporated by the application of the hot iron *before* it can arrive at sufficient temperature to coagulate the albumen. The same will also be the case with the albumen in its sticky state. Moreover, as I stated nearly two years ago, *no amount of dry heat* will coagulate or render insoluble a mere film of albumen, *even in its normal state*—it simply dries the albumen; therefore, the albumenized surface of a sheet of paper, whether it be rendered damp after being dried, or be taken before the albumen has ceased to be sticky, *cannot be rendered insoluble by the application of a hot iron*. By the aid of steam and boiling water, the albumenized surface of the paper may perhaps be made to imbibe sufficient moisture for coagulation to take place, but it becomes a question whether this coagulated moist albumen would return to a sufficiently dried state to be fit for photographic printing; but, even if it did so, I believe that this very insolubility would

render it almost—if not wholly—*incapable of being sensitized* by the nitrate of silver bath.

The belief in the fallacy that dried albumen could be coagulated, or even rendered insoluble, naturally induced means to be sought for to accomplish it; but, its being an impossibility, the beneficial effects produced by them were attributed to a cause which had no existence; and thus attention was diverted from the *real philosophy* of their action. "The rapidity with which a substance, soluble in water, is dissolved in it, is dependent upon its more or less hydrated state at the time it is submitted to the action of the solvent; thus, the passing a hot iron over the surface of albumenized paper, by desiccating it, renders it more difficult of solution; and, therefore, the nitrate of silver is enabled to be forming an insoluble compound before the solvent power of the water can come much into play.

Unfortunately, in making the sensitizing bath as we do at present, we use a solvent for the nitrate of silver, which is also a solvent of dried albumen; and thus, with respect to the albumenized surface of our paper, we have two antagonistic forces in operation at the same time—one having power to dissolve, and the other to form an insoluble compound. This being the case, we can diminish the power of either of them by increasing that of the other; and therefore it is perfectly possible, by sufficiently increasing the quantity of nitrate of silver, to almost (if not entirely) neutralize the solvent power of the water. The stronger the sensitizing bath the quicker will be its action, and the more will the albumenized surface of the paper be able to maintain its brilliancy; and I believe it to be possible to make the nitrate bath strong enough to render a mere drawing of the paper across its surface quite sufficient to form the albuminate and chloride of silver with the requisite quantity of free nitrate; and, from the solution not having time to penetrate the substance of the paper, that the prints will have *all* the brilliancy which albumen is capable of affording; and, moreover, that less silver will be wasted than at present, and less washing required; we should also, I believe, then receive the full benefit of colouration which the nitrates of the bases of the salting chlorides would give us. As alcohol is not a solvent of dried albumen its addition to the nitrate bath, by mixing with the water it contains, mitigates its solvent power in proportion to the strength and quantity added; hence the addition of alcohol to the sensitizing bath, and the desiccation of the paper by a hot iron, are *beneficial* because the solvent action of the water has been decreased by their means, and the albumenized surface is enabled to retain more of its brilliancy than it can do without their employment. It is scarcely necessary, perhaps, to say that alcohol must not be added in sufficient quantity to cause precipitation of the nitrate of silver.

In printing upon albumenized paper, it is usually considered that we have present *three* compounds of silver; the albuminate, chloride, and nitrate; and that the *chloride* is the most important of them. I do not hold this opinion myself, but believe that if the chloride be not deserving of being degraded to the *lowest* rank, it only holds a *secondary* one. That the chloride is not of that paramount importance usually attributed to it, is fully evidenced by the beautiful effects produced by the use of low salting formulae. The almost universally accepted theory respecting the production of the image, is, that the action of the light decomposes the chloride of silver, liberating the chlorine; and silver having a greater affinity for chlorine than it has for nitric acid, the silver of the free nitrate combines with this liberated chlorine, setting free in its turn the nitric acid and oxygen with which it had previously been combined; this decomposition and recombination of the chloride of silver going on during the whole time of printing: the vigour and intensity of the print being due to this constant and continued re-composition of the chloride of silver. According to this theory, the presence of the albuminate of silver is entirely ignored, and the free nitrate—as such—plays no part whatever in the production of the image. Were this the case, we could produce the same result by giving *at once* the same amount of chloride of silver as this additional re-composition has afforded, and dispensing entirely with any free nitrate; but experience tells us that this will *not* produce the same effect. I therefore hold the opinion that the nitrate of silver plays an important part *itself* in the production of the image: for surely it is too much to ask us to believe that the chloride can *only* produce a good effect when the nitrate is present; that is to say, that its continued re-production is necessary. The vigour of the print is not, I think, due to the chloride of silver, but to the albuminate; to which is also due the richness of tone. So little is understood of the

* PHOTOGRAPHIC NEWS, vol. vii. p. 5.

action of a solution of nitrate of silver upon dried albumen, that it has not yet been ascertained whether that which we term albuminate of silver, be a combination of the silver salt and albumen, or, a mixture of two compounds; one consisting of the acid of the salt and albumen, and the other of the base of the salt and albumen. Dr. Löwig says:—"If to a solution of albumen we add a solution of metallic salts, as sulphate of copper, nitrate of silver, bichloride of mercury, &c., precipitates are formed, which consist of albumen-metaloxyd and of the compound of albumen with the acids. The latter can be removed with water, whilst the albumen-metaloxyd remains undissolved."

I have said—"In printing upon albumenized paper it is usually considered that we have present three compounds of silver: the albuminate, chloride, and nitrate;" but I believe this idea rests only on assumption, as it has not been ascertained as a fact, whether sensitizing the dried chlorided albumen really produces two separate and distinct compounds of silver, the albuminate and chloride; or whether a double compound be not formed which, for distinction's sake, I will call a chlor-albuminate. The Abbé Pujos makes what I consider an almost astounding assertion respecting the formation of the image upon sensitized albumenized paper. He says:—"A proof when taken from the printing frame, is formed of three superimposed images—the first formed by the albuminate, the second by the chloride, and the third by the nitrate of silver." Supposing the chlorided albumen to be simply a solution of the chloride in albumen, without any chemical combination, we have still an intimate commixture of the two substances; and surely the new compounds formed by sensitizing will also be intimately blended with each other; but, if they be not so, what proof can be given to warrant the Abbé's assertion, that the albuminate will form the lowest stratum.

(To be continued.)

A SHORT LESSON IN PHOTOGRAPHY.—No. 9.†

As ambrotype resembles a melainotype in every respect; it is a positive picture to be regarded by reflected light, and is laterally inverted. The time required for the solar impression, and the mode of development and of fixation, are precisely similar as in the melainotype; the only difference between the two pictures is, that the ambrotype is prepared on glass, whereas the melainotype, as its name implies, is a picture on an iron plate. Inasmuch as the ambrotype is formed on the collodion film on glass, and that the latter substance is transparent, it becomes necessary to coat the posterior surface with either black varnish, black velvet, black paper, or, in fine, some black material to represent the dark background. It is almost immaterial which substance is used, as long as it is uniform in shade and texture; the proper varnish or cloth can be obtained from any of the regular dealers in photographic wares.

The ambrotype, thus prepared, is mounted with mat and preserver in the same manner as the melainotype, and inserted into its case. When thus mounted it can scarcely be distinguished from the picture on the iron plate. It is a much more tedious operation to prepare an ambrotype than a melainotype; for the glass in the first place has to be cleaned thoroughly, which requires much more time than to dust a new excelsior plate; then the varnishing with black japan, or the covering with black cloth, is an operation not required at all with the iron plate; so that, when both these disadvantages are taken into consideration together with the difference in fragility, lightness, and portability, operators give a decided preference to the melainotype, and have by this means almost pushed the ambrotype out of fashion. We will, therefore, leave it to its fate.

The next picture which claims our attention is the all-pervading card picture. No picture has ever had so wide a sphere of action, has gratified fashion and taste so long, or has been as productive of gain to the photographer, as the card picture. Every family, excepting mine, has its variegated album on the parlour table filled with family

likenesses from the time of Noah's ark down to the battle of Antietam—all of them, either staring right in your face as if they were suffering the last pangs of martyrdom, or as if straining a smirk whilst bitten by a flea. Family consanguinity in the present age of the world is circular—it has no limits—it is ubiquitous. Cousin Victoria, uncle Napoleon, great uncle Maximilian Joseph Ludwig, second cousin President Lincoln, nephew Colonel Ellsworth, my most intimate friend Lord Palmerston, General Beauregard, a distant relation of my wife's family (who is of French descent), General Kirby Smith (whose sister is a very dear friend of the family), Secretary Seward (the uncle of a lovely rich widow, now in Europe, on a tour with her medical adviser, for the benefit of her health and for her consolation after her heart-rending privations, and with whose little boys my dear little Joseph used to play at hide and seek in the Park)—together with an innumerable host of plebeian relatives and acquaintances, being part and parcel of our family pedigree: these, sir, you will find in our album on the drawing-room table.

This card picture is no ordinary picture; it is an extraordinary picture, and I will now tell you all about its manufacture.

The cards on which the prints are mounted, and which are denominated the "mounts," are each four inches long by two inches and one-third wide; these mounts can be had ready prepared, plain or ornamented with a gilt border, at the photographic ware establishments, whose advertisements you will find in this journal. The prints are smaller than the cards, leaving a margin of about one-tenth of an inch on the two sides and on the top; the margin at the bottom is about a quarter of an inch. The paper on which such pictures are printed is of the finest albumenized quality, that is, the texture of the paper itself is homogeneous and free from asperities, and the albumen is communicated to the surface uniformly and free from flaws. Some persons prefer plain salted paper for such pictures; but it is not advisable to make it your practice to print on such paper for such purposes, because you cannot obtain the same fine definition on a paper surface as can be obtained on an albumen surface. The prints in question present the model without inversion, being the result of solar printing beneath a negative. My task, therefore, resolves itself into that of taking a negative on glass.

Glass for negatives must be flat, homogeneous, free from flaws, and as transparent as possible; for card pictures it is cut to the quarter-size. The edges of each piece are ground, and the glass itself is prepared for the reception of the collodion, and in like manner sensitized, as already explained in a former lesson.

The developer may be either protosulphate of iron or pyrogallie acid. I do not use the same developer for negatives and positives. It is preferable to have less of the iron salt, in comparison with water, for a negative than for a positive, in order that you may watch the progress of the development easily, and also in order that you may flow the place entirely before the development commences. I use for my

Negative Developer.

Protosulphate of iron (pure)	40 grains
Water	4 ounces
Alcohol	2 drachms
Acetic acid	3 drachms

Or, No. 1.

Pyrogallie acid	12 grains
Acetic acid	1 ounce

(To be kept in the dark-room).

No. 2.

No. 1	1 drachm
Water	7 drachms
Alcohol	20 drops

(To be used immediately.)

* PHOTOGRAPHIC NEWS, vol. v. page 303.

† From *Humphrey's Journal*.

It is always recommended to filter both these developers before use. But, before we proceed to develop a picture, we must have the negative, and know all about taking it, and something of its philosophy. Instruction on these two points will form the subject of my next lesson.

The International Exhibition.

REPORT OF THE JURY ON PHOTOGRAPHY AND PHOTOGRAPHIC APPARATUS.*

FRANCE.

1458 BERTAUD (Medal).

1458 DEROGY (Medal).—To both of these exhibitors in the French department Medals were awarded. The first named received the award for an orthoscopic lens of very large diameter and excellent quality.

The lenses of Derozy were fully tested by the Jury, and proved highly satisfactory. An ingenious arrangement for lengthening and shortening the focus of the objective by the addition of a central lens, was found to answer admirably well for the purpose to which it was intended.

1459 BERTSCH, A. (Medal).—A Medal was awarded for a series of novelties in photographic apparatus. These consist of several automatic cameras with portable laboratory to facilitate the working of wet collodion out of doors without the necessity of a dark tent; also for a very excellent enlarging apparatus which he styles a "mégascope héliographe," the utility of which is illustrated by a variety of fine pictures enlarged from very small negatives. The collodion of this manufacturer is very good.

1457 DUBOSCQ, L. J. (Medal).—The apparatus for which a Medal was awarded in this instance, consisted for the appliances for using the electric light to photographic purposes, and a source of illumination for enlargement of pictures. It is stated that the specimens by NEMA-BLANC (1494) and VILLETTE (1456) were produced by means of this apparatus.

1451 TITUS-ALBITES (H. M.).—A manipulating laboratory camera, by which all the collodion process may be worked without any dark room or tent. The principle is similar to that of the original Archer's camera, but modified as regards the arrangements, which are very ingenious and deserving much commendation.

1476 BRIGIS, C. A. (H. M.). 1486 GARIN and Co. (H. M.). 1475 PUECH, L. (H. M.). 1493 MATHIEU-PLESSY (H. M.).

Honourable mention was granted to these exhibitors for general excellence of the various photographic materials which they exhibited, consisting of apparatus, photographic papers and chemicals. In reference to the chemicals, they deserve especial attention from the purity of the samples, as well as for the moderate price at which they are vended.

1490 HERRAGIS (H. M.) contributes a good assortment of lenses and photographic apparatus. His lenses have for a long time justly held a high reputation in France.

1482 KOCH (H. M.). This exhibitor is held in high estimation by his own countrymen, and the award is for general excellence of his apparatus.

1474 MARION (H. M.) contributes a variety of articles appertaining to the stationery of photography, consisting of albumenized paper, cases for preserving sensitive paper, albums, &c. These were all considered of great excellence.

1489 MILLET, A. (H. M.).—A variety of photographic lenses and fine pictures obtained by their aid are considered by the Jury well worthy of attention.

1473 ROLLOY (H. M.) exhibits a variety of good photographic chemicals and papers, also a varnish which, on trial, appeared to the Jury to possess many of the excellent qualities of the Söhne varnish.

36 KÜSS, A. (Medal).

HAMBURG.

PRUSSIA.

1420 BUSCH, E. (Medal).—Both contribute lenses for photographic purposes, which, on trial, were found to combine many excellent qualities in an eminent degree, and some were, moreover, distinguished by great cheapness.

1433 SCHERINGE (Medal).—The photographic chemicals of this exhibitor are well worthy of attention; they appear to be prepared with great care, chiefly for the supply of the retail houses. When purchased in any quantity these productions are very cheap.

1419 BEYRICH, F. (H. M.).—1427 KENZMANN (H. M.).

They exhibit many very fine samples of photographic papers, albumenized and plain. Results of a trial of several samples were very satisfactory, the proofs obtained being brilliant and perfect.

PICTURES.

We have already seen that great strides have been made in photography in the superiority of its processes; in the increased certainty which has been obtained by regard to the chemical condition upon which success depends; in the improvement of its apparatus, and the widened scope of its appliances, aided by increased skill in the manipulatory details. We now proceed briefly to refer to some of the examples of the various applications in which this progress was strikingly manifest.

Portraiture, as the most universal branch of the art, claims first attention; and here, in pure untouched photography, requiring no aid from the pencil of the artist, the most striking advancement has been made. Pre-eminent in this style are the vignette portraits of T. R. WILLIAMS (United Kingdom, 3182), to whom a Medal was awarded. In these, by the judicious arrangement of light, exact chemical conditions, skilful manipulation, and artistic management, a delicacy and perfection of representation is attained which at one time would have been regarded as impossible without the after touching of the pencil. Possessing many of the same qualities, combined with a richness and depth of tone due to the mode of printing, known as the ammonio-nitrate process, are the portraits by T. H. FLEMMING (United Kingdom, 3093). Similar in quality and in many points of excellence, but of larger size and bolder style, may be mentioned the portraits of M. Ken,

(France, 1500). In all these and some others delicacy is combined with great brilliancy, and those qualities which painters obtain by elaborate finish, are here secured by skilful manipulation guided by artistic judgment.

Another order of excellence, in which bold artistic conception is manifested with less attention to delicacy of manipulation, is illustrated by the productions of D. O. HILL (United Kingdom, 3996), whose portrait groups possess great merit.

The portraits of Ross and Thomson (United Kingdom, 3148) possess much of the freshness of design, and demonstrate that photographic portraiture need not be confined to the production of lifeless facial diagrams.

Untouched photographic portraiture, possessing many excellent qualities, both artistic and manipulatory, is exhibited by M. ALOPHE (France, 1462), and by M. NADAR (France, 1498), some of whose impressions have the additional interest of having been printed by means of the electric light.

M. ANGIEA of Vienna (Austria, 670,) exhibited a series of very large portraits, in groups, vigorous, brilliant, and artistic; they illustrate the fact, that the highest qualities are not incompatible with an amplitude of size not usually attempted in photographic portraiture.

K. STRAEGLE (Denmark, 133) contributes many portraits of similar excellence to those described; one possessing especial interest at the present moment in the eyes of the nation is a portrait of the Princess of Denmark, in which the charms of the photograph are much enhanced by the beauty, grace, and intelligence which it so faithfully depicts.

(To be continued.)

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 11th March, 1863.

MESSIEURS DAVANNE and GIRARD have undertaken a series of researches upon the fixing of proofs by means of sulphocyanide of ammonium, as proposed by M. Meynier. They first tried its action upon albuminate of silver, and found that it was much more energetic as a fixing agent than hyposulphite of soda. If a certain quantity of albumen be precipitated directly by nitrate of silver, and after the precipitate is washed, and treated two or three successive times by sulphocyanide of ammonium, the residue carefully washed, we recognise that this residue dried and be calcined leaves only very minute quantities of silver in the ashes, while, in operating in a similar manner with hyposulphite of soda, the ashes contain, relatively, considerable quantities of silver. The sulphocyanide of ammonium appears, therefore, to present a real superiority over hyposulphite of soda in respect to the absolute fixing of the whites of the proofs.

Sulphocyanide of ammonium can be made to replace cyanide of potassium and hyposulphite of soda in all their applications. It dissolves, with the greatest facility, all the salts of silver employed in photography: chloride, bromide, iodide, &c. In the state of concentrated solution it fixes negatives very rapidly, and employed of the strength of 15 to 18 per cent. of water, it serves to fix positives.

It is a substance which readily crystallizes in fine white deliquescent crystals. M. Meynier can obtain it in very considerable quantities in his manufacture of ammoniacal salts, and the recent discovery by M. Gelis allows us to assume that this salt may be manufactured at as low a price as hyposulphite of soda. It presents the advantage over the latter of being less easily decomposed, and while the slightest trace of acid puts the sulphur of the hyposulphite of soda at liberty, and compromises the proofs, there need be no such fears in employing sulphocyanhydrate of ammonium. It is, therefore, a substance which merits the attention of photographers; it must be carefully studied, and although the first laboratory experiments appear to have been perfectly successful, yet long and extensive practice may show some inconveniences attending its adoption, but among its known advantages we may place in the first rank that of allowing the operator to handle indifferently negatives and positives, fixing baths, &c., without incurring stains or any other risk.

S. M. the Emperor has bestowed the cross of the Legion of Honour upon three photographers whose productions were most deserving attention in the late Universal Exhibition, viz., M. Bayard, for useful photographic inventions, M. Duboscq, for improvements in optical instruments, and on M. Poitevin, for his inventions in carbon printing and in photolithography.

* Continued from p. 119.

M. Beaujout suggests the following, in connection with printing enlarged positives, not as a new discovery in photography, but as a new application of a phenomenon lately described by Dr. Sabatier, with regard to direct positives on glass. Every photographer knows how difficult it is to obtain a perfect positive, either in the camera or by direct contact from a negative intended for enlarging: they also know how difficult and tedious it is to take enlarged positives from a small negative, the sky being so rarely clear. We avoid all these inconveniences by applying Dr. Sabatier's discovery.

Take an enlarged positive on wet collodion from the negative (the exposure is instantaneous in the sun), and develop it with pyrogallie acid, and, in causing diffused light to act upon it at a given moment, the enlarged positive may be converted into an excellent negative, by means of which as many positives may be obtained as required.

M. Davanne, in quoting Mr. Kibble's method of obtaining nitrate of silver, remarks that an analogous result may be obtained by keeping the nitrate of silver fused at a dull red heat for several minutes, a slight decomposition takes place; a part of the nitrate of silver probably passes to the state of nitrite, and another part is reduced to a very finely-divided metallic state; by afterwards making a warm solution we may rapidly obtain the reaction indicated by Mr. Kibble.

M. Licsegang remarks upon intensifying, that when the negative is completely developed by the dilute solution of sulphate of protoxide of iron, then washed, it is immersed in a bath containing 2 parts of cyanide of potassium, 0.4 of nitrate of silver, and 100 of distilled water. The picture fixed in this solution is carefully washed and intensified by the following process:—

In a litre of water dissolve 9 grammes of bichloride of mercury, and when the solution is complete add 25 grammes of iodide of potassium, pulverised. Shake until completely dissolved, then filter and keep for use.

When it is desired to intensify a proof, a small quantity of this solution is put into a glass, and thrice its volume of water added to it, and poured on and off the proof several times; and when the desired intensity is obtained, it is thrown away and replaced by a solution of hyposulphite of soda of 10 per cent., which gives both a deep tone to the proof and fixes it at the same time.

IRON DEVELOPMENT FOR DRY PLATES.

SIR,—Having found the mode of developing dry plates by means of pyrogallie acid without the addition of acid or silver, very successful, I thought that an iron developer applied in the same manner would produce a like effect. On trial I found that such was the case, the picture developing rapidly and evenly. When the image is fully out, the plate must be well washed and intensified in the usual way, with pyro and silver. The iron developer may be about 20 grains of the sulphate to the ounce of distilled water, *without any acid*.

Lime water will develop tannin pictures. The best way of using it is to immerse the plate in a bath containing the lime water. A mixture of lime water and tannin will also develop pictures taken by the Fothergill and other dry processes.—Your obedient servant, THOMAS M. LEAHY.

Dublin, 4th March, 1863

PANORAMIC PHOTOGRAPHS ON FLAT PLATES.

SIR,—In the last number of the NEWS, mention is made of some panoramic negatives on flat plates, exhibited at the late meeting of the London Photographic Society, and, as the subject appears to be at present attracting considerable attention, you will perhaps be able to find space for an account of the method by which I succeeded in producing such pictures, rather more than a year ago.

If an ordinary camera have a screen of pasteboard, or other opaque material, with a vertical slit about half an inch

wide down the middle, fitted inside the back of it, just in advance of the focussing screen, and be then directed at any convenient objects, and slowly turned on its stand, it will be seen that the view will appear to pass slowly across the narrow portion of the focussing screen, on which alone it can fall, with the vertical lines absolutely upright, and that the vertical dimension of the field will be the diameter of the circle of light given by the lens.

If now, by any contrivance, a sensitive plate can be caused to move in the same direction as the view appears to move on the focussing screen, and at precisely the same rate, it is evident that we shall be able to obtain a picture whose vertical angular extent is the angular diameter of the field of the lens, and of any horizontal length we please, this being limited only by the length of the plate.

This I have managed to effect in several ways, the simplest and most beautiful of which I proceed to describe.

An ordinary camera, furnished with a short focus lens (a Dallmeyer's stereoscopic would answer admirably), whose equivalent focus must be known with extreme accuracy, has the ordinary groove for its slides removed, and the end filled up with two pieces of wood, so as to leave only a narrow vertical opening between them down the centre of the field.

A back to hold the plate must be constructed like an ordinary stereoscopic back, but of a size to suit the dimensions of the picture to be taken, and with a shutter to work horizontally a little more than *twice* the length of the slide.

A vertical opening corresponding in dimensions with the opening in the back of the camera is made in this shutter across its middle; and on the sides of this opening are fixed two projecting slips of wood, which enable the shutter to be firmly fixed to the camera by biting the edges of the slit, precisely as the sides of the ordinary camera back slide into the groove in the camera. The shutter being thus fixed to the camera, it is evident that every part of the plate can, by sliding the frame along the shutter, be brought successively opposite the opening in the back of the camera.

A circular disc of well-seasoned wood or metal, is now to be made, with a shallow groove round its outer edge, the *radius* of the disc being made *exactly equal to the focal length of the lens*; this is the point of most importance in the whole contrivance, as any error here will prevent us from obtaining perfectly sharp pictures. This disc is to be fixed firmly on the head of the tripod and carefully levelled, and in the centre of the disc, and exactly concentric with its edge, must be a vertical proof made to fit into a socket in the bottom of the camera, so that when the camera is mounted on the disc, and turned round about the vertical axis of the pivot, the axis of rotation shall pass through the optical centre of the lens, and the axis of the lens shall be truly horizontal.

At one portion of the circumference of this disc, is to be attached one end of a very fine and flexible wire, somewhat longer than the plate frame, and the other end of this wire is to be fastened to a short arm, which is firmly fixed to the plate-frame, so that as the camera is turned round on the disc, the wire wraps round the outer edge of the disc in the shallow groove, and by this action causes the plate-frame to slide along the shutter at precisely the same rate as the image formed by the lens moves. If, therefore, a sensitive plate be placed in the plate-frame, taking care to slide the frame to one end of the shutter before bringing it out to the light, and the frame and shutter fitted on to the camera, and the wire attached, by simply causing the camera to revolve on its pivot slowly and uniformly, the successive portions of the view will be unwrapped and straightened out as it were on the flat plate, and if the opening at the back of the camera be not too wide (about one-tenth of the focal length for single lenses), a panoramic picture will be produced, of exquisite sharpness and beauty, and a perfect cylindrical projection of the scene, equal in accuracy, and vastly more useful to artists and military engineers than the queer looking catharine wheels produced by Chevallier's Plane Table.

I have left some minor points of detail unexplained, but the above is as brief and intelligible as I could make it without diagrams, and I shall be happy to give you any further information on the subject, if you think it sufficiently interesting to your readers, and to send you a specimen of the work it will do.

I forgot to mention, that by modifying the shape of the opening, a longer or shorter exposure can be given to any portion of the picture lying in a horizontal direction.—I have the honour to be, &c., &c.,
W. G. T. P.

[We shall be glad to learn further particulars, and to see a specimen of the results.—Ed.]

IODIDES AND BROMIDES IN COLLODION.*

An acetic acid bath is, in its first stage of sensitiveness, not appreciably, if at all, inferior to a nitric acid bath with ripe bromo-iodized or iodized collodion, but it is less stable than the nitric acid bath, and, eventually, capricious. It deteriorates much sooner, and is not easily rectifiable.

An acetate of soda bath, in its best state, is an accelerator of collodion, however iodized or bromo-iodized, but it is very capricious and rapidly deteriorates. I do not know how to rectify it.

A carbonate of soda bath is a superior accelerator, but it also is unstable like the last. In its sensitive state, however, it is well fitted for instantaneous work with ripe iodized or bromo-iodized collodion, and for iron development. The collodion being made of the ammonium and cadmium salts.

I beg to observe here, that when I talk of iodized collodion, I invariably mean, iodized with combinations of cadmium and ammonium, or cadmium and potassium; and when I allude to potassium, or ammonium, or cadmium iodizers, I always name them, and this will now prevent a misapprehension of my meaning.

Mr. Ponting, I see, holds the same opinion that you do—that a nitric acid bath is fatal to iodized collodion. A reference to his experiments will clearly show that he used $\frac{1}{2}$ drop of nitric acid to each ounce of bath. An excess of acid will, as is well known, diminish sensitiveness, and otherwise cause injury. And if Mr. Ponting's iodizer was ripe, the $\frac{1}{2}$ drop of acid per ounce was too much; for ripe collodion containing cadmium, as his does, works in a bath verging on neutrality.

Mr. Ponting's acetic acid and soda baths were but faintly or appropriately acid, and consequently the iodizer answered better with them. "The bath No. 1, with acetic acid and acetate of soda, was unmistakably the quickest of the three, the nitric acid bath, No. 2, being very slow."

If it is asked how this nitric acid bath, unsuited to the iodizer because of excess of acid, answered for the bromo-iodizers? I beg to reply that not one of the bromo-iodizers was constituted like the iodizer. There was no equality of conditions. Like Mr. Blanchard, Mr. Ponting made but one solitary experiment, and may or may not have pitched upon each collodion in its most serviceable condition.

If I can get heard, I feel convinced that the results of my experiments will be well received. I have no object in misleading any one, I have honestly stated all the conditions of my experiments, and challenge their all-possible fairness being disputed.

As illustrative of my experiments, let me recommend the following to any one desirous of testing them. Take a collodion of reliable quality from a good maker; iodize it with cadmium 3 grains, ammonium $1\frac{1}{2}$ to 2 grains; and for a bromo-iodizer, cadmium 3 grains, ammonium $\frac{1}{2}$ to 1 grain, bromide of ammonium 1 to $1\frac{1}{2}$ grain. Try these with a nitric acid bath, and acetate of iron developer, from time to time, and record the results; one subject, one lens, and one hour for both samples being understood. When the bath does not work satisfactorily, make a new one. Continue the experiments until the collodions begin to deteriorate. A comparison of the recorded results will show greater durability and sensitiveness in the iodizer. Other experiments may be made with different proportions of salts, and by reducing or increasing the quantity of bromide. The results will be as those stated under the heads A to D in my last letter, and I earnestly beg that they may not be considered untrustworthy until practically proved to be so.

I will conclude here with a hint regarding the nitric acid

bath. It must always be rectified for the bromo-iodizer, and it will then answer equally as well for its pair the iodizer. If the bath were rectified for the iodizer, precaution would perhaps not always prevent a possible excess to the hurt of the bromo-iodizer, especially if the quantity of bromide present is large, when this would, of itself, be a weakener and retarder of sensitiveness in a very marked manner. Taking the bromo-iodizer, then, as a regulator and key of the bath, is not wrong, nor need the plan create any apprehension of a possible deficiency of acid for the iodizer; for, with any given collodion, however so salted, it is not easy to ascertain exactly what quantity of nitric acid can exist in excess, or be deficient in a bath without appreciable injury to a plate; and this fact meets also the case of any accidental deficiency or excess in rectifying the bath at starting for the bromo-iodizer. And, above all, when we reflect that the pair iodizer and bromo-iodizer, to be compared, are of absolutely identical constitution in the plain collodion used, and in the proportions and bases of the salts used; and that ripe collodions, whether iodized or bromo-iodized, work in a bath verging on neutrality, the condition of the bath is, to all practical considerations, if not theoretical also, admirably adapted to both the iodizer and bromo-iodizer compared. If the correctness of these principles is concurred in, let them be compared with those adopted by Messrs. Ponting and Blanchard in the treatment of their baths for iodizers and bromo-iodizers not similarly and identically constituted.

I will not here recapitulate the articles of my belief. They can be seen under the heads A to D of my last letter; but I will only add that I nowhere condemn the use of bromides, regarding which, in page 479 of the PHOTOGRAPHIC NEWS, will be found the following.—"But although the use of a bromide is attended with loss of sensitiveness, the more appreciable as the quantity is larger, compared with simply iodized collodion, yet its presence in collodion is very desirable, because of its established sensibility to coloured light; and it simply remains for operators to regulate the quantity according to requirements, remembering that there is scarcely a subject which will not benefit by its presence in suitable strength. Of course the iron developer must be used."

By iodized collodion, here, is meant collodion iodized with combinations identically as the corresponding bromo-iodizers compared with it. And I would also recommend the perusal of my remarks at the beginning of col. 2, page 479, regarding the exquisite sensitiveness of chemicals when even a large addition of bromide is not accompanied by any appreciable loss of sensitiveness.

I think it is quite clear that I too swear by iron and bromo-iodizers, under certain qualifications, however, which but require examination to secure concurrence and general approval.

I am sorry that I should take up your time and space; but it is for the last time (if you so wish it). It is impossible to dispose of the present subject in a few lines. It has so many apparently contradictory features, that they defy collective treatment. The popular theory involved has hitherto been eluded and confounded with the popular practice. The former, which has never had a leg to stand on, has been sustained by arguments erroneously deduced from the latter.

I am not putting this question of iodides and bromo-iodides in a new light, but in one in which it has never before been properly viewed. I must meet with opposition from all those who have not been accustomed so to look at the matter. It is not possible to expect a cradle-faith to be abandoned without a struggle, unless, indeed, the principle of Mahomedanism is brought to bear on it; but this will not do with photography.

There should be no alarm at my efforts because directed against a pet, but unquestionably erroneous and untenable, theory, which most photographers have never examined, but been content to receive as correct, viz., that bromides are accelerators. They are, indeed, the very reverse, and answer successfully and admirably as drags. I am not singular in this view, and I have given proof enough to be tested by everybody. Mr. Hardwich, with a mind singularly free from prejudice, has pronounced bromides retarders; but he nowhere objects to their use—on the contrary, he recommends them, although retarders. I, also, have advocated their use. But while I uphold the practice proper, I attack the theory popularly expressed. And why should not error be exposed?—I am, dear sir, yours truly,
AUGUSTUS WEBB.

Talk in the Studio.

PHOTOGRAPHIC PIRACY.—On the 4th inst., at Clerkenwell Police Court, *William Luff*, a photographic artist, residing at 325, City Road, was summoned before Mr. Barker, at the instance of Mr. Ferdinand Joubert, to answer the following complaint: "For that you, on the 17th day of January, not being the proprietor of copyright in a certain photograph, to wit of a photograph of H.R.H. the Prince of Wales, did unlawfully sell and offer for sale a copy or colourable imitation of the said photograph, without the consent of the said Ferdinand Joubert, the proprietor of the subsisting copyright in such photograph, and knowing that the said copy of such photograph had been unlawfully made contrary to the statute," &c. A gentleman from the office of Mr. Bowen May, solicitor for the prosecutor, said it was not intended to proceed with the case, as the defendant had signed the following declaration: "Mr. Joubert,—In consideration of your releasing me from the payment of any but 40s. damages towards the expenses of my solicitor, I promise never to offend again by selling any more printed copies of your photographs, and, if I break this engagement, I promise to pay you fifty pounds, by way of liquidated damages; and I declare I am not aware where I purchased the printed copies of the distinguished persons I have copied; and I also declare that I have no other copies than those handed to your solicitor, WILLIAM LUFF. Witness, J. Bowen May, 67, Russell-square."

PHOTOGRAPHY AND THE ROYAL WEDDING.—Public celebrations in our day are perpetuated by an unerring recorder which the grandest pageants of olden times lacked. Photography is the sworn witness of all public spectacles, and has been very active in all the recent public ceremonials. Many scores of brass tubes took aim at the youthful and fair Dane, who having before invaded many loyal hearts, came on Saturday to take possession of her conquest. Mr. Francis Bedford and Mr. Downes were at Gravesend to photograph the arrival; Mr. Blanchard took some instantaneous stereo negatives of the same ceremony. Many others were engaged in London, with what success we have not heard. The ubiquitous photographer even found his way into St. George's Chapel, at Windsor, to record the wedding ceremony, Mr. Vernon Heath having, we believe, been honoured with that commission. Not least attractive amongst the many tastefully decorated buildings in the city on Saturday was the Photographic Warehouse of Messrs. Henry Squire and Co., in King William Street, the noble circular front of the building having a fine balcony erected and ornamented with great taste. The warehouse was for the nonce turned into a theatre, with tier above tier of seats, accommodating a hundred persons with a most excellent view of the procession. Mr. Squire had issued photographic tickets, containing portraits of the Prince and Princess, inviting a large number of friends connected with literature, photography, and art, to witness the spectacle. When it had passed, it was announced that a successful instantaneous negative had been obtained from the top of the building, prints from which would be placed in the hand of each guest as a souvenir of the occasion. Of the other interesting parts of the entertainment offered to the guests, in which both wet and dry processes were tried, plates coated and cleaned with amazing rapidity, it is unnecessary to speak here. We need only add, having ourselves been present, that the results were most satisfactory. We learned, from the long examination which a pause in the procession afforded us opportunity for, that the numerous photographs which have crowded shop windows, have not done the young Princess anything like justice. Her fair hair, brilliantly rosy complexion, and the winning grace which lights up her delicate features of pure Scandinavian type, are not fairly rendered in any portrait we have seen.

To Correspondents.

G. F. R.—The first application of albumen and gelatine in combination with a bichromate for the purposes of photolithography of which we have any record was made by Mr. Osborne, who used it in 1859. The process is not protected by patent, and you may use it without let or hindrance. The fact that it is included in a patent by no means implies the validity of the patent. Nine-tenths of the photographic patents, indeed, a large proportion of the existing patents of all kinds, would be proved invalid if brought to the test of law.

H. L.—Unless the paper be good in itself it cannot give good results when albumenized. We have seen some samples of Saxe paper with streaks or

bands which were unusually absorbent, such paper would inevitably give imperfect results even when albumenized. In the case you describe another sample of paper is the only remedy.

J. W.—A yard only 20 feet by 15 feet in dimensions, surrounded by walls, the lowest of which is 15 feet high, is a rather unpromising place for photographic portraits. The only mode of preventing the undue action of top light will be to place a screen over-head, so that all light shall be cut off which does not reach the sitter at an angle of 45°.

S. M. Tou.—Your design for a colorless collodion bottle is doubtless ingenious, but as the sediment generally possesses a greater specific gravity than the collodion, it would be apt to flow from the bottom the moment the bottom of the bottle was elevated in the act of pouring.

Mr. Wright.—Vignette photographs are almost as old as photography itself, and were occasionally produced on the Daguerreotype plate before the collodion process was discovered. Mr. Harner has not, that we know of, made any claim for the invention of vignettes, nor even of the mode of double printing he has worked with such skill. The plan of double printing Mr. Harner unquestionably was the first to carry out to the same degree of perfection, but in its simpler forms it had been practised for many years. We must demur to the claim of priority or superior excellence you make for Mr. Watson, unless substantiated by proof.

S. W., Dudley.—In photographing engraved or cut-glass vessels you can get the same effects upon your plate which you can see with your own eyes; but if the vessels be transparent you can necessarily see through them to some extent, so that the cutting of the far side, as well as that which is nearest the eye will be seen. If you wish the front of each decanter only to be photographed, it will be necessary to cover or conceal by some means the other side. The best mode of lighting will be to place them at some distance from a window, so that the direct light reaching them may be tolerably well diffused, to give a soft light on one side and a soft shadow on the other. Use a bromo-iodized collodion, expose sufficiently long, and develop with iron.

A YOUNG PHOTO.—In making collodion, proceed in the following order, for, say 4 ounces:—Take 16 grains of soluble cotton, place them in your 4-ounce bottle, and add 1 ounce of alcohol, sp. gr. 820. Next take 8 grains of iodide of cadmium, 8 grains of iodide of ammonium, and 4 grains of bromide of cadmium; dissolve these in 1 ounce of alcohol of the strength before mentioned. When these are dissolved, filter the solution into the bottle containing the cotton and alcohol. Shake until the cotton is well saturated, then add 2 ounces of pure sulphuric ether; shake until all is dissolved. Then let the collodion stand for 24 hours, when it will probably be fit for use, and will be very sensitive. In making larger quantities, it is better not to add the iodizing solution until the normal collodion has been decanted from any sediment.

SUBSCRIBER T.—Acetate of soda is soluble in three parts of cold water; a saturated solution would consist, therefore, of one ounce in three ounces of water, a strength unnecessary in photographic operations. 2. Sulphuric acid which has become black has come in contact with organic matter; it may still be used for some purposes without disadvantage, but you cannot undertake to purify it. 3. Citric acid, when added to the printing bath to remove the colour, is used in no larger quantity than is just necessary to cause a slight precipitate, as, being tribasic, it rapidly wastes silver. 4. Sulphide of potassium added to a hypo bath for precipitating the silver is added until there is no further precipitate thrown down, the quantity necessary being determined by the amount of silver present. 5. Bicarbonate of soda is soluble in ten parts of water, therefore, 3 drachms will require $4\frac{1}{2}$ ounces of water to dissolve all. 6. The same principle applies here; you attempt to dissolve a substance in less water than is necessary for its solution; phosphate of soda is soluble in 4 parts of water, and, therefore, 5 drachms would require at least 2 $\frac{1}{2}$ ounces of water to dissolve all, whilst you have only used 2 ounces. 7. Sulphide of potassium is used to precipitate the gold from a hypo bath; protosulphate of iron from an alkaline toning bath.

NOTTING HILL PHOTOGRAPHERS.—We always feel pleasure in advocating the interests of every class of photographic operatives; but we must remind our readers that the bargain between employers and employed, whether it refer to the hours of labour, the work done, or remuneration received, is entirely a personal question between the parties to the contract. We strongly recommend liberality to employers as good policy, and because photography is generally sufficiently remunerative to justify liberality. But on the other hand it should be borne in mind that in winter a photographer's working hours are necessarily short, and that no available light should be wasted in summer. We do not think there is much danger of over-work or under pay in the present state of the profession, inasmuch as the market is not so much stocked with thoroughly skilled workmen to induce any of them to accept injustice. Where there is a good demand for any class of labour it will always command a fair price for reasonable hours. An employer who, under such circumstances, attempted to grind his people would soon find them leaving him for more liberal employers. Whatever grievance of this kind exists must soon right itself. We cannot offer a more definite opinion without knowing more of the circumstances, and hearing the case stated by both sides.

H. D. O'DONNELL.—The note and cash received. We will endeavour to carry out your wishes. Several Correspondents in our next.

ENAMELLED AND TINTED PAPERS FOR PHOTOGRAPHERS.

It has often been said that a photographer needs to be a "Jack-of-all-trades;" it is probable that he will shortly have to add a knowledge of one more business to his miscellaneous stock of information: we refer to the trade of a fancy stationer. Tinted papers and enamelled papers are already in the market, and likely to command considerable attention, and we expect perforated cards, lace envelopes, and other specialities of the fancy stationer to follow.

Some of these things are really worthy of serious attention. We recently received from Herr Paul Liesegang a sample of paper, which, he informs us, is becoming popular amongst German photographers. It is called "enamelled paper," and is intended exclusively for card portraits, and similar small pictures. The surface very nearly resembles that of the well-known enamelled visiting card, which is generally produced by means of a preparation of lead. The instructions for manipulation are simply to proceed in all respects as with albumenized paper. We have printed a few card pictures upon the sample sent, following those instructions, and are highly gratified by the result. The paper appeared a little more sensitive than most samples of albumenized paper; printing rapidly with a rich red brown tone. They toned satisfactorily in an acetate of soda and gold bath a few days old, losing very little depth, either in toning or the subsequent fixing. We tried different tones, from a rich warm purple and a warm grey, to a deep fine black, free from any inkiness; in each case the colour being rich and deep, with a very agreeable warmth. The prints were, moreover, very brilliant, having both more vigour and more half-tone than some other prints from the same negatives on albumenized paper, the fine surface rendering with exquisite delicacy all the half-tone in the negative. There is, moreover, entire immunity from mealiness.

As to the mode of preparing this paper, we have no information, and can only speak from observation. The final surface appears to be chlorided albumen; but, instead of having been applied to a plain Saxe or Rive paper in the usual manner, the paper seems to have been varnished or enamelled in some way first, so that the albumen, instead of sinking into and partially permeating the paper, rests entirely on the surface; thus securing an important condition for brilliancy of image. If the paper be sponged or soaked in water before exciting, a surface of albumen can be removed, but an enamelled surface is found underneath. If an air bubble occur in exciting, the spot, after fixing and washing, is not plain paper, like that found under similar circumstances with albumenized paper, but still a varnished or enamelled surface. Of what the primary surface may consist, we cannot at present state; we can only remark, that it is insoluble in water and alcohol. So far as we can at present judge, it forms no combination with the silver during floating, and the image appears to be confined entirely to the surface of albumen; thus presenting a similar result to

the paper previously prepared with india-rubber. How far it may be equal to the latter we cannot say, as we have not made any comparative trial at present. Whether the paper is yet in the English market or not, we cannot state; but it will, doubtless, speedily find its way into the hands of dealers, and for card pictures is well deserving of a trial; for, whilst for large pictures we hold a glazed surface as vulgar and inartistic, for small delicate pictures like card portraits the objections are by no means necessarily the same.

Another kind of fancy paper for photographs has been attracting some attention lately. We refer to the rose-tinted albumenized paper. We must confess that we do not look with much favour upon its use. But tastes differ, and there are some subjects which may possibly be improved by the tint, especially if it be very delicate. Hard negatives sometimes also yield better results on a paper with a tint than on a pure white surface. Some other advantages are claimed for it, regarding which, however, we have had no experience. A correspondent writes to us, saying, that some tinted paper supplied by Mr. C. E. Elliott, gives him better results, and is more sensitive, excited on a forty-five-grain bath, than ordinary albumenized paper on an eighty-grain bath. The mere presence of colour could not, of course, effect the improvement, which must have been due therefore to other causes.

If a tint be desirable at all, it must be a much better plan to apply it after the completion of the printing operations, so that the exact character best suited to the print may then be easily determined. This will also remove a difficulty which we are informed in some cases occurs, namely, the disappearance of the colour during printing operations. We subjoin, therefore, a communication with which Mr. Lampray, of Paternoster Row, has obliged us, regarding his own experiences in the application of a tint to the finished picture. Here it is:—

DEAR SIR,—I have had a host of inquiries as to "tinted" paper and the practicability of tinting the picture *after* it is finished, instead of colouring the paper before it is albumenized. The information I have been able to give—the result of a few trifling experiments that I have made—seems to have afforded satisfaction to a good many of my correspondents. Perhaps you will not think some remarks upon the subject quite useless in your columns as others will thereby be enabled to avail themselves of what information I possess. The extremely little leisure left me by a daily and rapidly increasing business must be my excuse for the somewhat crude form of my communication.

I need scarcely say that it is manifestly an advantage, if tinted prints are desired, that the printer should have it in his power to tint them to any shade, and of any colour his fancy, or the necessity of the case, may dictate. He may, for instance, by adopting a suitable dye, tint his picture so as, in some fashion, to match the complexion of his sitter. This he could not do if he used paper tinted before printing, unless he had papers previously prepared not only of various colours but of different shades of each colour. And even then he could not be sure of obtaining the exact shade he desires, as a great deal of the

colouring matter comes out in the toning—and does his toning solution no good.

The plan I have tried is very simple, and any one can easily adopt it. The dyes I have used are known as "Judson's Simple Dyes," and may be had of any chemist, at sixpence per bottle. Six pennyworth would tint, I dare say, half a ream, or thereabouts, of paper. A little of the dye, according to the depth of tint desired, should be mixed in boiling water (stirring it up well with a glass rod), and the print should then be immersed in it for a few minutes. This should be done after the print has been fixed and *thoroughly washed*, and before it has been allowed to dry, otherwise it may make the paper rather rotten. Some colours get a little deeper on drying.

Some pictures I happened to have by me were toned to a peculiarly ugly colour. After tinting them in the way I have described, they were converted into very presentable, if not really good, prints. On an emergency, therefore, tinting in this way may be of great importance to the artist.

With care and a little practice, different parts of the picture may be tinted with different colours.

Hard, inky-looking prints improve by tinting.

A mauve tint gives a very good effect to landscape *stereos*.

I have produced one or two curious results in the course of my experiments, and on some future occasion, after further trials, I shall have great pleasure, should you accord me space, in laying them before your readers.—I am, dear sir, yours faithfully,

THOMAS LANPRAY.

44, Paternoster Row, London, E.C.
March 12th, 1863.

Judson's dyes are sold in small bottles at sixpence and upwards. There are several tints prepared, such as magenta mauve, scarlet, orange, blue, green, brown. A tea-spoonful of the dye added to a couple of quarts of boiling water will produce a tolerably vivid dye of any of the colours. For the rose tint, recently introduced in albumenized paper, the magenta dye answers admirably. The print, when completely washed and ready for drying, should be immersed in the dye and left for a few minutes. It should be borne in mind that the longer the immersion the deeper the tint becomes. A very dilute solution of the brown gives a fine india tint, which is, to our taste, the least vulgar of any colour for a picture, and may, indeed, in some cases, with advantage, take the place of white. In portraiture for instance, wherever a negative is hard, yielding black and white pictures only, a delicate india tint removes much of the effect of hardness, and is, in some cases, very pleasing. The mauve tint, or a mixture of mauve and magenta, will please some persons, and it is possible other mixtures may find a use. But there is one word of caution to which we beg especial attention; whatever the tint used, let it be as delicate as possible, or it will inevitably be offensive and vulgar. Let it be a tint and nothing more, never approaching a full hue. And bear in mind that the tints deepen very much in drying, they must not, therefore, approach the desired colour when wet, or they will be too dark when dry. It is not improbable that by skillful management these dyes might be used for tinting photographs in various colours, as they are perfectly transparent, but we do not enter into the subject at present.

Since writing the above, we see that Mr. Sutton has prepared a series of "Photographic Tints" to be used in a similar way for a similar purpose. He also adds another suggestion—to perfume the photograph. "Fancy," he says, "sending by letter your card portrait tinted and perfumed. Is not the idea exquisite?" Perfuming the photographs! Well, why not?

A FINAL WORD ON ART-PHOTOGRAPHY AND ITS CRITICS.

SOME weeks ago we gave a resumé of the opinions of the art-critics upon photography with a few brief comments on these opinions. Since then, our pages, and those of some of our contemporaries, have been considerably occupied by an amusing discussion on the subject, which has well nigh exhausted it. Mr. Rejlander has been quaint, humorous, modest, and forcible, in his defence of the claims of his art.

Mr. Wall has been trenchant and unsparing. Mr. Robinson has been terse and good-humouredly caustic. Others have spoken or written on the same side. The art-critics having done their business, we do not, of course, hear any more of them. Mr. Sutton has once or twice returned to the subject, but as we do not find him defending his original propositions, we conclude of course that he has abandoned them. We the more readily come to this conclusion because in his last number he treats the subject with infinite drollery. Referring to the authorities quoted by Mr. Wall to prove that truth was an important element in art, he says of a marble statue, "Why not have a little *more* truth, and paint it flesh colour, and put a wig of real hair upon its head, and give it glass eyes?" Now, when Mr. Sutton speaks of a wig and glass eyes as *truth*, he is of course joking; for have not these, from almost time immemorial, been regarded as typical of falsehood, and is not a wig commonly called *false hair*? Of course, Mr. Sutton is joking, and a good joke is often an excellent thing to aid in abandoning an untenable position. The truth is, Mr. Sutton has a real appreciation of art-photographs, and we have seen few photographs more artistic than some produced by himself.

There is just one point in the argument to which we will refer now. An important distinction we find continually overlooked in these discussions. It is customary with the opponents of the art claims of photography to confound *high art* with *fine art*, and because photography is unsuited to the one, to argue that it is incapable of the other. No one that we have ever known has claimed for photography the capability of competing with high or ideal art. Jokes about Michael Angelo or Raphael engaging in photography are therefore altogether beside the mark. No one ever dreams of expecting works of imagination from photography, and the most ardent art-photographer would as soon think of comparing one of Madame Tussaud's wax figures with the Moses of Michael Angelo, as of comparing the best photographs with Raphael's Transfiguration. But is there no fine art but ideal art? If so, what are the works of Landseer, Frith, Ansdell, Creswick, Stanfield, Hook, Linnell, Brett, McCullum, or a host of others whose especial charm is *truth* in the delineation of nature? To deny to photography a position amongst the fine arts because it is not ideal art is then clearly foolish, as by pushing the argument to extremes we must exclude by the same argument all the productions of artists whose pride and boast is to paint only from nature.

We do not intend, however, to enter into any further discussion here of a question which to us appears so self-evident: but before entirely leaving the subject, we should like to call the attention of our readers to a large engraving of Mr. Robinson's last composition "Bringing Home the May," which appears in the *Illustrated News* of the 28th ult., accompanied by some remarks reiterating the former criticism in that journal, protesting against the want of harmony in tone in photographs, and arguing that they cannot be in "any true sense pictures." Now we simply want our readers to mark the fact, that according to the canons of these critics the engraving before us is a work of art, whilst the photograph from which it is taken is not and cannot be. Yet we unhesitatingly challenge conclusions on these two pictures. The photograph is full of tone and gradation, the chiaroscuro is almost perfect and the whole is most harmonious. The engraving is as unlike as it is possible to be and at the same time be a copy. It is a crude, inharmonious mass of spotty lights and black shadows without gradation, tone, or harmony in any sense of the word. But this is art, and Mr. Robinson's original is photography.

ENGLISH AND FRENCH INTERNATIONAL COPYRIGHT IN PHOTOGRAPHS.

Few persons are aware that, although an original photograph be first published in the United Kingdom, the copyright in such photograph may now be secured in France,

and *vice versa*. As photography has grown into a branch of industry, and photographic copyrights are of considerable value, it may be useful to call attention to the existing state of the laws of England and of France affecting such copyrights.

Formerly, when any work of literature or of the fine arts was first published abroad, the copyright in it became public property in England. The author was unable to obtain any protection there in respect of such copyright. This manifest injustice has been remedied by certain Acts passed in the reign of Her present Majesty, "to amend the law relating to international copyright." These statutes enable the Crown, by order in Council, as respects works of literature, music, and art (to be defined in such order), and which shall be first published in any foreign country named in that order, to direct that the authors of such works, and their assigns, shall have the privilege of copyright therein to the same extent as allowed by law in respect of any such works first published in the United Kingdom. But no such order is to have any effect unless it states that due protection has been secured by the foreign power named in the order, for the benefit of parties interested in works first published in the British dominions similar to those comprised in such order. Besides this, as a condition precedent to the acquisition of any copyright in a work so first published abroad, the statutes render it imperative that the work shall be registered at Stationers' Hall, together with the date and place of first publication thereof abroad. The time within which such registration must be made after that first publication is to be fixed by the order in Council.

In 1852 an International Copyright Treaty was entered into between England and France, whereby it was agreed that "the authors of works of literature or of art, to which the laws of either of the two countries do now, or may hereafter, give the right of property or copyright, shall be entitled to exercise that right in the territories of the other of such countries for the same term, and to the same extent, as the authors of works of the same nature, if first published in such other country, would therein be entitled to exercise such right." But the treaty expressly stipulates that such international copyright shall not be claimable in either country, unless the work shall have been registered," viz. :— "1st. If the work be one that has first appeared in France, it must be registered at the Hall of the Company of Stationers in London; 2nd. If the work be one that has first appeared in the dominions of Her Britannic Majesty, it must be registered at the *Bureau de la Librairie* of the Minister of the Interior at Paris." At the time of such registration "one copy of the best edition, or in the best state," must also be deposited; and "in every case the formality of deposit and registration must be fulfilled *within three months after the first publication of the work in the other country*." The treaty likewise provides that "a certified copy of the entry in the register-book of the Company of Stationers in London shall confer within the British dominions the exclusive right of republication until a better right shall have been established by any other party before a court of justice;" and that "the certificate given under the laws of France proving the registration of any work in that country shall be valid for the same purpose throughout the territories of France." The charge for registration of a single work "shall not exceed one shilling in England, nor one franc twenty-five centimes in France; and the further charge for a certificate of such registration shall not exceed the sum of five shillings in England, and six francs and twenty-five centimes in France." The ten years' term for which this treaty was entered into has expired, but it provides that it shall continue in force "from year to year until the expiration of a year's notice from either party for its termination"—an event which in the present advanced state of public opinion respecting international rights generally, and copyright particularly, appears to be most improbable.

In pursuance of this treaty, and of the powers vested in the

Crown for that purpose, Her Majesty afterwards made an order in Council, whereby it was ordered "that from and after the 17th day of January, 1852, the authors, inventors, designers, engravers, and makers of any of the following works (that is to say), books, prints, articles of sculpture, dramatic works, musical compositions, and any other works of literature and the fine arts, in which the laws of Great Britain give to British subjects the privilege of copyright, and the executors, &c., of such authors, &c., shall, as respects works first published within the dominions of France after the 17th January, 1852, have the privilege of copyright therein for a period equal to the term of copyright which authors, &c., of the like works respectively first published in the United Kingdom are by law entitled to; provided such books, dramatic pieces, musical compositions, prints, articles of sculpture, or other works of art have been registered, and copies thereof have been delivered according to the requirements of the International Copyright Act (7 Vict. c. 12 s. 6) within three months after the first publication thereof in any part of the French dominions."

Soon after entering into the above convention the French law was placed upon what seems to us, having regard to the existing state of the law of nations, to be the only just, and, consequently, tenable ground respecting international copyright. Irrespective of any reciprocity, a decree was made upon the 28th March, 1852, prohibiting within the dominions of France the piracy of works published in any foreign State, and also the importation or exportation of any pirated copies of such works.

Now, with respect to copyright in *photographs*, no such copyright existed according to the law of England prior to the 29th July, 1862, when "The Copyright (Works of Art) Act" came into operation. Since that date the authors of original photographs, or the employers of such authors, are entitled to copyright therein *for the author's life and seven years after his death*; but to acquire the benefits of that statute, the work must be registered at Stationers' Hall.

So likewise, according to the decisions of the French Courts, no copyright in *photographs* has until recently been held to exist in France. According to the Code Napoléon, "*L'auteur d'un ouvrage de littérature ou de gravure, ou de toute autre production de l'esprit ou de génie qui appartient aux beaux-arts, en aura la propriété exclusive*"—or copyright, during the life of such author, also of his widow, and for thirty years after the death of the survivor of them in favour of their children.

Does a *photograph* come within the above definition of the French law relating to works of fine art? Some of the most eminent French artists have protested against the art of photography being deemed a fine art; and until within the last few months it seems that the French Courts were of the same opinion. But the decisions upon the point have recently been overruled by the supreme court of appeal in France, the Court of Cassation, in a case which arose out of the piracy of a photographic portrait of the late Count Cavour. It was held that although a mere servile copy of any subject made by means of photography is not absolutely a work of art within the meaning of the Code, yet that a photograph does become a work of art, and is the subject of copyright, when its execution includes artistic conception upon the part of the author.

Practically, therefore, British photographic artists will now be enabled to obtain the benefits of copyright in France for most of their original works. If claimed under the Copyright Convention with France, to which we have alluded, it will, however, be subject to the performance of these conditions: 1st. The work must have been first published in the United Kingdom. 2nd. It must have been registered, and a copy deposited, in Paris, *within three months* after such first publication.

Upon the other hand, it seems French photographic artists may now secure a British International Copyright in all their original photographs upon these conditions:—1st. The work must have been first published in France. 2nd. It

must have been registered, and a copy deposited, in London, within three months after such first publication.

Considering the beauty of, and the immense demand for, many photographic works produced both in France and England, the existing state of those international relations to which we have called attention seems calculated largely to enhance the value of original productions of that description by French and British artists.—*Athenæum*.

CHEMICAL EXPERIMENTS.

FORMATION OF NITRATE OF SILVER FROM AN IMPURE SOURCE, WITH SEPARATION OF IMPURITY; THE SAME FROM PURE SILVER, WITH PROOF OF THE ATOMIC THEORY.—PAPER RELATIVE TO THE ABOVE, COMPRISING GENERAL REMARKS ON THE SENSITIZING BATH.

By JOHN KIBBLE.*

In the present advanced stage of our Society, it will doubtless appear to many of you a retroceding, on my part, in entering into a subject with which all of you are supposed to be familiar. Such an opinion, to a certain extent, will really be correct; yet, from the numerous queries put to me by photographers and others, many practical difficulties must exist—not so much, perhaps, in the preparation of the new silver baths as in the reduction of the old solutions, which have become unfit for use by general deterioration, such as acidity, foreign matter getting admittance into it by some unknown means, or from any accidental cause whatever. I think it will best forward the object I have in view to commence with the preparation of nitrate of silver from an impure source, such as the silver alloy of commerce, which will not only show the formation of nitrate of silver, but the very simple manner in which the copper or any other impurity can be separated and a pure salt obtained, and, if desired for instantaneous work, brought to its greatest state of alkalinity by fusion.

Before doing so, I will enter into a few particulars regarding the tendency which all bodies have to combine in definite proportions with each other when entering into chemical union. So fixed and invariable is this, when all circumstances are alike, that the term "law" has been adopted to express the fact. The chemical atom must not for one instant be confounded with the atom of the philosopher, or that infinitesimal portion of matter supposed to be indivisible. The latter is purely imaginary, and, although affording a wide field for ingenious speculation, is of very little consequence to the present purpose; the former is an absolute fact, proved by gravitation, and visibly demonstrated through the medium of the finely-adjusted balance. Until such an instrument was resorted to, chemistry, that matter-of-fact science, had in it much that was hypothetical.

Oxygen—that body which plays so important a part in the economy of the universe in which we dwell—exists in combination with hydrogen in the proportion of eight of the former to one of the latter by weight, forming that well known and absolutely necessary fluid, water. Assuming the combining proportion or atom of hydrogen as unity, it necessarily follows, the atom of oxygen being eight times heavier than the former, when they enter into chemical union with each other the resulting atom of water must be nine. For example: take eight grains, by weight, of oxygen, one of hydrogen, and having ready a glass tube of the requisite capacity, sealed at one end, filled with water, place it on a shelf in the pneumatic trough, the open end a little below the line of the water. Having done so, pass into it the gases in the above proportions. Pass an electric spark through the tube: chemical union will at once take place, accompanied by detonation and light—simple manifestations of combination. The water from the trough will rush into this tube, filling it, showing that the gases no longer exist. Repeat this experiment, say with ten grains of oxygen to one grain

of hydrogen. Upon the electric spark being applied, the gases will again combine in their atomic proportions; but, in this instance, it will be observed that the water does not fill the tube, but leaves a space equivalent to the vacuum occupied by two grains of oxygen. Upon a quarter grain of hydrogen being added, and the electric spark applied, the water will rush into and fill the tube as in the first instance, proving the gases will only combine in the ratio of eight to one, or their atomic proportions; could they be forced to combine in any other proportions the result would be no longer water.

Let me now take the metal iron. If fifty-six grains of it in a very finely divided state, be enclosed in a bulb tube of the following shape, the exact weight of which is known

—having fixed it to some support so that the flame of a spirit lamp, or better still, if at command, a Bunsen's gas burner, can be applied to the bulb containing the iron until such time as the mass is ignited to redness—the flame of an additional lamp must now be applied to the flask containing water, attached, as you observe, to the end of the tube, until the water undergoes ebullition, keeping a continual stream of vapour passing over the red hot iron. The affinity of the metal for oxygen will cause decomposition of the vapour, the oxygen thereof uniting with the iron forming the peroxide: the released hydrogen passing off with the superfluity of vapour can be collected, if means be used for that purpose. Allow the glass vessel to cool, and, after ascertaining that there is no adhering moisture, the whole can be carefully weighed. It will now be found to have increased exactly twenty-four grains in weight; two atoms of oxygen which have attached themselves to the metal forming the peroxide of iron = eighty grains. This is in chemistry termed a synthetic experiment, or the formation of a compound from the elements of which it is composed. Now comes rather a paradoxical point. Detach the flask containing the water and add thereto some iron filings and a small quantity of sulphuric acid: replace it again: this, by the decomposition of water will yield hydrogen, which, as it passes over the heated oxide will rob it of the oxygen, the pure metal being left the same as at the starting point. This is called an analytical experiment, or the resolving of a compound into the elements of which it is composed—the exact converse of the former. This is an exceedingly interesting experiment. In the first instance, iron under the influence of heat decomposes the vapour of water, becoming itself an oxide, the hydrogen passing off free. In the second instance, the oxide of iron under heat parts with its oxygen to the hydrogen, the two gases combining to form water, the pure metal coming into existence once more. There is something very singular here. In the first experiment the iron tears the oxygen from the hydrogen: in the second, the hydrogen tears back the oxygen from the iron. This can only be explained by quantity; that is, the great volume of hydrogen passing over the heated oxide, every atom of which is struggling for its atom of oxygen, the joint force empowers the affinity existing between the metal and oxygen, which, in the act of splitting up, is seized upon by the hydrogen in atomic proportion—the result being water, the iron left pure. You will also observe that when these two gases are presented to each other in the nascent state—that is, immediately on being let loose from other combinations—they at once enter into chemical union; whereas, if collected in separate vessels and allowed to get into a state of repose, and then presented to each other, they will mix

* Read at a meeting of the Glasgow Photographic Association, March 5th, 1863.

mechanically, but not combine, unless other means are employed, such as a flame of the electric spark. May not this be analogous to what photographers experience with sensitive surfaces which are not developed within a given time after having been submitted to actinism? or with the iodide of silver surface which has been left too long in the nitrate of silver bath after decomposition has been thoroughly effected?

With the little I have said, unless you have yourselves practised such experiments, you must exercise faith. With what is to follow, that may be discarded: there stands the material, which you can test by gravitation.

For the first experiment I shall take the atom of silver = 108—in the *present instance* grains—which you must take as the standard of all that follows, unless contradicted.

When nitric acid— $\frac{1}{11}$ $\frac{5}{43}$ —is poured over this, decomposition of part of the acid ensues. Eight grains of its oxygen combine with 108 grains of silver, forming the oxide of silver, = 116, at *one and the same instant*: the oxide is dissolved in the free undecomposed portion of the acid, forming nitrate of silver in solution = 170 grains; that is, 54 acid, 116 oxide, of which you now have visual evidence. All the free acid being now evaporated, you have the nitrate as an amorphous mass. On the temperature increasing, you observe the mass enters into fusion, which, if carefully done will show a decidedly alkaline reaction with litmus paper. Having so far as I have proceeded given proof of the atomic theory, I will now dissolve the nitrate in distilled water, and give you an additional proof of what is termed substitution, viz., that the atom of one metal will displace from solution, the atom of another.

You are already aware that the present solution contains exactly 108 grains or the atom of silver. To displace that I use one atom of copper, = 32 grains. You now observe that having heated the solution, and kept the copper wire rotating in it, to shake off the adhering deposit of silver, already in the space of a few minutes all the metal is thrown down. I now withdraw it, pull it through the folds of a towel to clean it, and very slightly heat it to drive off moisture. It now weighs, as I anticipated, exactly 32 grains less than at first, = one atom of copper, which is now in combination with the acid formerly holding the silver in solution. The atom of copper can now be displaced by the atom of iron or zinc; but time does not admit of that, nor is it all necessary. It is imperative in experiments of this nature that no free acid be present in the nitrate solution, otherwise it will be a source of error in many ways. It would dissolve more than the atom of copper, and therefore could be called a case of substitution: even could the copper be withdrawn immediately all the silver had fallen, the free acid would again take the finely-divided silver into solution.

For the present I will lay aside the pure nitrate solution and commence with the impure, precipitating the silver therefrom by substitution. This will not only give a very correct idea of the quantity of alloy, but will show the separating, washing, and formation of pure nitrate of silver from an impure source, such as the photographer has often to deal with. In this part of my experiments I have to work at considerable disadvantage, the vessels being much too small to give the thorough washing and boiling necessary to deprive the silver precipitate of its adhering copper. I find in my own experience that silver precipitated from strong solutions is infinitely much worse to free from copper than when displaced from weak solution, and are apt to show traces of copper when re-formed into the nitrate of silver, even although the latter washings were alternately with weak acids and ammonia; but when separated from weak solution, and boiling water is used in washing, a very pure salt can be obtained—in as short a time, and with as little trouble, or less, than by any other mode I have tried—such as the chloride, carbonate, oxide, &c. I have a strong impression that silver in precipitating rapidly from strong solutions embodies in its substance traces of the nitrate of copper,

which only again get loose on the breaking up of the metal, such as in entering into solution; if so, the slower the precipitation the better. With a proper arrangement of the copper, a pound weight of silver could be thrown out of solution just as rapidly as one ounce, and with as little labour.

To iodize the bath, the simplest mode is to dissolve the crystals of the nitrate of silver in three or four parts of water, and add about fifteen grains of nitrate of silver to each ounce of the quantity weighed. This will immediately disappear. But in reducing the solution to the strength of thirty or forty grains per ounce fluid, a considerable precipitate of iodide of silver will be displaced from solution, showing over-saturation at that strength. This will also show that a bath, although saturated with iodide of silver at the strength the photographer works with, when used for long exposures, such as enlargements,—more especially if the temperature be high, the evaporation of water from the nitrate of silver covering the sensitized surface,—must, of necessity, increase it in strength—indeed sometimes to saturation, when it will at once attack the iodide, taking it into solution, thereby rendering the film porous, and round the edges of the plate almost transparent.

If there be any point which I have not lucidly expressed, or which you may consider erroneous, please to bring it under discussion.

THEORY OF POSITIVE PRINTING.—ALBUMENIZED PAPER AND THE ACTION OF THE SENSITIZING BATH.*

BY GEORGE PRICE.

THERE is what I consider to be *another fallacy* which requires a passing notice, the belief in which has prevented any endeavour to ascertain whether it be not possible to obtain different—or better—tones than we do at present: I mean the belief that the base of the salting chloride has no effect in giving colour to the print; that the nitrates produced from these bases *cannot* have any effect, may be according to a *pre-conceived* theory, but it will be very evident that *it is contrary to fact* to any one who will watch the different hues produced by ammonium, sodium, and barium, provided *they make use of their eyes*. I ask, then, would it not be advisable to ascertain whether there be no nitrates, the addition of which will yield purple, black, or rich brown tones, according as the subject might require. Evidently the belief in this fallacy arises from what I also consider to be an erroneous idea as to the manner in which the double decomposition takes place when the dried chlorided albumen is sensitized by the nitrate of silver bath. According to an assumed theory, when the decomposition of the salting chloride takes place, the chlorine remains in the albumen, drawing to itself the silver from the bath; whilst the liberated nitric acid and oxygen, being left behind by the silver, draw to themselves, *from the paper*, the base of the salting chloride which the chlorine has liberated in consequence of its own greater affinity for silver. The chloride of silver being, therefore, formed *in the albumen*, and the nitrate of ammonia, soda, or baryta, as the case may be, being formed *in the bath*. Stating it shortly, it is assumed that the *re-composition* of the *new chloride* takes place in the paper, and the *re-composition* of the *new nitrate* in the bath.

When theories are at variance with facts methinks it is time that they were abandoned and others formed more in accordance with the results which practice exhibits; but instead of doing so, so tenacious of life is a fallacy, that we find persons who, although unable to deny the facts, are compelled to confess that they are at a loss to account for their existence, because they still persist in viewing them through the medium of a *pre-conceived* theory. Thus, in the celebrated controversy which took place about two years ago, respecting "the testing of used silver baths by the hydrometer silver meter," Mr. Dawson, the present lecturer on photography at King's College, stated,† that "*theoretically* the large amount of other nitrates arising from the double decomposition, must *necessarily* accumu-

* Continued from p. 128.

† PHOTOGRAPHIC NEWS, vol. v. p. 116, and BRITISH JOURNAL OF PHOTOGRAPHY, vol. viii. p. 103.

late to such an extent as to render the hydrometer test useless;" and doubting the assertion "that such an accumulation did not *practically* take place, except to a very limited extent," he afterwards analyzed some old baths in order to satisfy his own mind on the point. Consequently, in a paper he subsequently read upon the subject, in allusion to one of these baths, he says*—"I should certainly have expected to find a very much larger proportion of nitrates different from that of silver. The equivalent of nitrate of soda being 84.97 (say 85), it follows that, for every two grains of nitrate of silver abstracted by decomposition, one grain of the former *ought* to be left in the bath. In the above case, certainly, and in some other baths I have tried, this accumulation of nitrate of soda or ammonia did not take place in any way commensurate with the quantity *we ought to expect*. Although these nitrates must inevitably be found, they are partly retained and taken away by the paper, *in a way which I am at a loss to account for.*"

Again, persons have assumed that the nitrate of the base of the salting chloride does not affect the colour of the print, and though an intelligent use of their eyes cannot fail to tell them the contrary, they still adhere to this idea, and endeavour to find *another cause* for the colouration which they cannot gainsay. Thus, Mr. Hardwich, in the last edition of his *Manual of Photographic Chemistry*, page 479, in speaking of chloride of barium, says:—"It also slightly alters the colour of the photographic image when used in preparing positive paper, which may be due, in some measure, to a chemical combination of baryta with albumen." That it is the *nitrate* of baryta which produces the alteration of colour, is evidenced, I think, by the fact that it takes place in a much greater degree in *plain salted* paper, than it does in albumenized; in *plain salted* paper the *black* colouring property of nitrate of baryta has not to contend against the *red* colouring of albumenate of silver, and no albumen being present, the peculiar colouration *cannot here be produced by its combination with baryta*. This theory of the nitrates of ammonia, soda, and baryta being formed in the bath, I believe to be based upon assumption, and *to be contrary to fact*. I maintain that the double decomposition and recombination takes place *on the surface of the paper*; the nitrate of silver solution leaves the vessel which contained it and adheres to the surface of the paper, permeating the film of dried chlorided albumen; I am therefore at a loss to conceive why theory should *grant* to the chloride of silver the privilege of being formed on the paper, where its constituents are present, but should *deny* the same privilege to the nitrate of ammonia, soda, and baryta, whose constituents are *also* present there. Whatever nitrates, otherwise than silver, are found in an old sensitizing bath for paper, I believe find their way there in consequence of a too long floating *having dissolved them out of the albumenized surface of the paper* where they had *originally* been formed.

The philosophy of positive printing upon albumenized paper is really such a comprehensive subject, that it would even be a vain attempt for any one with far greater abilities than I am possessed of, to endeavour to treat it satisfactorily in a paper which must necessarily be circumscribed in its length, in order to afford time for after discussion. I have, therefore, omitted *even an allusion* to those necessary accompaniments of printing—*toning and fixing*—and confined myself to the action of the preliminary sensitizing bath; for, had I not done so, I must have encroached *much more* upon your time and attention, and I fear that you may think it has been trespassed upon too much already; moreover, I deem that I have already furnished you with quite enough matter for an evening's discussion.

As a question naturally fixes attention to its own individual subject, allow me to state in that form, the various points which I consider particularly require elucidation, and upon which I invite your opinions:—1st. *What salting chloride* for the albumen is the best to use, and why? Also, is a combination preferable to a single one? if so, what, and why? and what proportion should the chloride bear to the albumen? 2nd. *How* does the nitrate of the base of the salting chloride influence the colour of the print? 3rd. *Supposing* the albumenized surface of the paper be capable of being rendered insoluble *previous to sensitizing*, would that insolubility be an advantage; or, would it not tend to diminish—or destroy—its capability of being sensitized by the nitrate of silver solution? 4th. *Supposing* we use a *very strong* sensitizing bath, is the vigour of the print dependent upon the length of time the albumenized paper is floated upon

it; and does its employment necessitate *deeper printing* than a weaker bath does? 5th. In sensitizing a sheet of albumenized paper, are *two separate and distinct* compounds of silver formed, viz., the albuminate and chloride; or, is a *double compound* formed? 6th. *Supposing* two distinct and separate compounds of silver be formed by sensitizing, which of the *three* compounds of silver on the paper is the most important in the production of the image—the albuminate, the chloride, or the nitrate? What part does *each* play—and do they act conjointly or independently?

I do not mention the opinions I have advanced respecting dried albumen, and the manner in which the double decomposition and recombination is effected when we sensitize a sheet of chlorided albumenized photographic paper, because they can be discussed incidentally with the points I have named.

In all philosophical discussions, but more especially when the subject is but little understood, mere *assertion* will never tend to enlighten us, however high an authority the person making it may be considered; for we have had too many instances of men of science being led into grievous error and promulgating most extraordinary fallacies as facts; every gentleman, therefore, who gives his opinion upon *any* points that arise in the discussion, will, I trust, state the *reasons* which induced him to form them, as he thereby gives the others an opportunity of showing whether they are fallacious or not. For the better elucidation of these points, I think I should be allowed the same privilege that counsel are, viz., that of *cross-examination*, which I will promise not to use rigorously. With this suggestion I now leave the subject in your hands to deal with in the manner you consider best.

ADDENDUM.

This, Mr. President and Gentlemen, is what I wrote for our last meeting, but its having been unavoidably postponed, a short addendum is now necessary. A paper has since been published in the journals, by M. Davanne and Girard, "On the Action of Nitrate of Silver upon Albumen,"¹² they state:—"The combination of albumen with nitrate of silver varies according to the strength of the silver bath. Thus in treating five cubic centimetres of albumen with five grammes of nitrate of silver, we obtained very different precipitates, according as those five grammes of silver were dissolved, so as to form solutions of 15, 10, 5, 2½, or 1 per cent. With the solutions of 15 and 10 per cent., the albumen is strongly coagulated; it gives a heavy, abundant precipitate, which may be collected on the filter in the form of distinctly separate pellicles. With weak solutions of silver, the quantity of the precipitate is much less considerable. A notable quantity of albumen remains in the bath in a state of solution. The portion precipitated is soft, glutinous, and sticky."

This is an announcement that every one who knows anything at all about the subject, has been fully aware of *long ago*. If an egg be boiled what we deem soft, the white has very little consistence, but this consistence increases up to the point at which the yolk becomes, by boiling, what we designate hard; the albumen is then, what, for want of a better expression, I will call *saturated with heat*, and thus is perfectly coagulated; it is only therefore to *this* state that the term coagulated properly applies. The same, also, with respect to the combination of albumen with nitrate of silver. Albumenate of silver is, correctly speaking, only that combination of albumen which takes place when it is *saturated with nitrate of silver*, every combination *below* this is what may be considered as an *imperfect albumenate*. Common sense tells us that, as varying approximations to perfect coagulation are afforded by varying degrees of heat, so differing proportions of nitrate of silver must produce differing approximations to the perfect albumenate of silver.

I am ever willing to confess that I have formed an erroneous idea, when that idea is proved to be incorrect. I have, therefore, now to state that I have hitherto been in doubt whether, if the albumenized surface of a sheet of photographic paper were rendered insoluble *previous to sensitizing*, this insolubility would not almost destroy its capability of being sensitized. This doubt is now dissipated, for Mr. Simpson has kindly furnished me with a piece of albumenized paper, the surface of which, Mr. Wood, of Edinburgh, has rendered insoluble by the aid of steam. This paper does not *appear* to have lost any of its capability of yielding either the albumenate or chloride of

* PHOTOGRAPHIC NEWS, vol. v. p. 116, and BRITISH JOURNAL OF PHOTOGRAPHY, vol. viii. p. 103.

* PHOTOGRAPHIC NEWS, vol. vii. page 53.

silver, by sensitizing. A comparatively weak nitrate bath will, of course, produce good effects upon it, provided it be of sufficient strength to saturate the albumen in the ordinary time of floating, as a strong bath is only necessary when the albumen is soluble, because by hastening the time when insolubility occurs, it prevents the solvent power of the water having full effect.

Ever since I have known anything of photography, I have been firmly convinced that the nitrates of the base of the salting chloride, affects the colour of the print; although this has been strongly denied, the belief that such is the case has been daily gaining ground, and in Mr. Towler's "Lessons on Photography," No. 11, published in *Humphrey's Journal*, I now find my statement corroborated. In allusion to plain and albumenized paper, prepared for photographic printing, he says:—"The chemical foundation in either, is an alkaline chloride, which by floating the paper on nitrate of silver, or ammonia nitrate of silver, becomes converted into chloride of silver, in a state of very fine division, mixed with the nitrate of the alkali employed. The latter salt modifies in a great measure the colour and intensity of the print produced. From this circumstance, we account for the different tones in different specimens of prepared paper. Some manufacturers use chloride of ammonium, others that of potassium, sodium, or lithium, in the salting of their paper; each print, on this account, will have a different tone when it leaves the printing frame."

Under the title, "Coagulation of Albumen," I find in the leading article of the *British*, for Feb. 16th, some statements of the editor's, which require a passing notice. Alluding to MM. Devanne and Girard, he says:—"They go into another phaso of the question, which has disturbed the equanimity of our antagonist, Mr. George Price—we mean that of the amount of albuminate of silver, in comparison with the chloride, produced upon a piece of positive photographic paper, on being sensitized on the nitrate of silver bath." Now, there is not a single word of truth in any part of this assertion; the whole of it is such pure fiction, as not to have even the shadow of a fact for its foundation. I am no antagonist of Mr. Shadbolt in any way whatever, not having as yet entered into any controversy with him; and moreover, my antagonism is against fallacies, and not against persons. I was the first person who drew attention to the erroneous ideas prevalent respecting the coagulation of dried albumen; and I believe also, that I am the only one who has calculated from an atomic weight, the amount of albuminate of silver on a sheet of albumenized photographic paper; and how my equanimity can possibly have been disturbed by so doing, I am at a loss to imagine, I only know that it has not been so in reality, for nothing I have ever written respecting the impossibility of coagulating dried albumen, has yet been disproved, although I have publicly challenged any one to do so. Mr. Shadbolt takes an exceedingly lofty flight in the realms of fiction, when he states the subject of MM. Davanne and Girard's investigations to be "the amount of albuminate of silver in comparison with the chloride, produced upon a piece of positive albumenized paper on being sensitized on the nitrate of silver bath;" the plain matter of fact being that their paper has no reference whatever to the amount of albuminate of silver in comparison with the chloride; they investigate simply "the action of nitrate of silver upon albumen," without any reference to either the alkaline chloride on the paper before sensitizing, or the chloride of silver produced by its being sensitized; and they state merely that varying strengths of the nitrate of silver solution produces varying degrees of coagulation of the albumen, and therefore varying compounds of albumen and nitrate of silver; a previously well-known fact. Because I calculated according to a particular atomic weight, it is a strange perversion of logic to assume, as Mr. Shadbolt does, when he says that its combination in other proportions is "an idea apparently ignored by Mr. Price." It happens, however, that for more than twenty years I have been well aware of the different character of the precipitates which varying strengths of solutions of metallic salts produce when mixed with albumen.

Mr. Shadbolt also says:—he alludes to the subject "for the purpose of discussing the accuracy or otherwise of certain propositions advocated and maintained by the editor of a contemporary and one of his correspondents, in opposition to certain others held by ourselves and one of our contributors." As what I have written appeared in the NEWS long before the *British* took any notice of the subject, I cannot have stated opinions "in opposition" to certain others held by its editor and one of its contributors; moreover, Mr. Shadbolt is the only person who

has written in the *British* on the subject, and then it was only in reply to a letter of mine, when, amidst much misrepresentation and personal abuse of myself, he denied that this contributor entertained the opinion I had attributed to him in that letter. What I wrote respecting the non-possibility of coagulating dried albumen was corroborated by Mr. Simpson before this; and it must be borne in mind that I commenced writing about albumen two years ago, although it is only lately that I have succeeded in arousing attention.

Mr. Shadbolt also says:—"It has been contended by one or both of our opponents that albumen, in contact with nitrate of silver and some other metallic salts, does not undergo coagulation, but merely combination with the metallic base." I am sorry to say that there is also not a word of truth in this statement; neither Mr. Simpson nor myself have ever said or written anything of the kind; and as Mr. Shadbolt has not ventured to gainsay aught that I have advanced, and has not published his opinions upon the subject of albumen, we cannot be his "opponents." He proceeds to say:—"We, on the contrary, maintained that there was no evidence to show that coagulation did not come about contemporaneously with combination, and cited several authorities in support of this view." This statement of what he himself wrote in his own former leader, is also pure fiction; Mr. Shadbolt maintained nothing whatever of the kind he now says he did, nor did he cite any authorities to the purport he states; in what he did say on the subject he merely attempted to show that coagulation and insolubility were considered as synonymous terms, and to prove it he cited an authority who said nothing upon the subject.

I have reluctantly felt compelled, in justice to myself, to take this notice of Mr. Shadbolt, and much regret to find that such gross misstatements and fictions can emanate from the editor of a scientific journal which claims to hold high rank amongst its contemporaries. With an apology for the extra length of time my addendum has claimed your attention, I now leave the proposed questions in your hands, to discuss in whole or part, or not at all, as you think best.

ON THE ELECTRICAL THEORY OF PHOTOGRAPHY.

BY JOHN JOHNSTONE.*

I STAND before you, this evening, with much diffidence; and, if I should fail in imparting information to recompense you for the time devoted to me, I trust you will vent your disappointment on your fellow-member, my friend Mr. J. E. Mayall; but, should the contrary be the case, he is no less entitled to your vote of thanks for his impertunity in inducing me to appear before you. The subject announced is the electric theory of photography. It might possibly have been better if announced as an electric theory of photography, as several others have been nibbling at the same bait; but, so far as I know, no one has as yet developed a great principle as a foundation upon which to build with certainty. It is my intention this evening, if possible, to lay a firm foundation on which scientific workmen may build a superstructure sound in all its parts. I have had some doubt in my mind as to the best mode in which to introduce the subject, being aware that many of you are well versed in every department of knowledge bearing on photography; yet, from my own experience, in conversing with photographic friends, I have found a great difficulty in making them clearly comprehend the nature of electrical polarisation. If you will bear with me a short time, I will lay before you a few facts in connection with my own impressions as to the nature of heat, electricity, and light.

When a boy at school, it was a habit with some of the more mischievous to cut a metal button from their coat, rub it on the desk, and then apply it to the cheek or back of the hand of their neighbour. This produced a startling effect, often eliciting a retort not very pleasing to the offender. But simple as this experiment may seem, it lies at the basis of electric phenomena. Let us vary the experiment a little by drawing the button rapidly, with a certain amount of pressure, over about eighteen inches of the surface of the facia of a painted architrave of a door. We find that adhesion of the button is the consequence. How is this to be accounted for? In the first instance we have heat generated between a conductor and a partial non-conductor of electricity by friction or abrasion. In the second case we have the same thing, a little modified; in drawing the button along, we generate heat, but the two bodies are not equal con-

* Read at a meeting of the Photographic Society (London), March 2nd, 1863

ductors of electricity; we find that the metallic button has lost a portion of heat in its transit, thereby creating a polarised condition, causing an attraction between the two bodies. Let us now turn to the phenomena exhibited by the electrical machine in its ordinary working, having the silk rubber amalgamated in the usual way, and a metal conductor connected with the glass cylinder, and a similar one connected with the silk rubber. On turning the handle, heat is generated; but, as the glass and silk have unequal attraction for electricity, the heat is split up into a positive and negative condition, accumulating in the two conductors. Let us now attach a wire to each conductor (having the whole machine insulated) bringing the other ends nearly in contact; here the charged conductors have transferred their charge of electricity to the points of the wire, where it is palpable to our senses, as light and heat—this flow of electricity may be made to do duty chemically for any length of time, proving clearly that the earth is not necessary for the continuous supply of either the positive or negative element. After exciting the machine, it will be found that the glass cylinder is quite neutral, the whole of the developed electricity being concentrated near the ends of the wires. If a conductor is charged positively, and any other body (either solid or gaseous) be brought nearly in contact, an induced electrical condition is the result—that is, the part of the body nearest to the conductor will be in a negative condition, and the other extreme in a positive one—leaving the centre of the intermediate space quite neutral.

Now let us turn our attention for a short time to the action of the galvanic battery in the production of electricity. It is well known that if a plate of zinc and of copper are brought in contact for a short time, and then rapidly separated, the zinc plate indicates positive electricity, showing that the copper has parted with a portion of its constituent electricity. Let us now connect these two plates with a wire, immersing them in a solution of salt slightly acidified, or water only with a little acid to increase the conducting power—we now see a continuous flow of electricity resulting in chemical action; on tracing the current we find that the copper has, in the first instance, yielded a portion of positive electricity to the zinc—the zinc being in a state of tension polarises the intervening fluid or electrolyte—hence the negative element of the fluid unites to the positive electricity of the zinc—the positive element uniting with the negative copper thus producing a normal condition between the copper and zinc, so that a continuous supply of electricity is kept up from the copper to the zinc. It is rather difficult to comprehend the state of the polarised fluid; but, as an assistance, let us imagine a tangible image by supposing while the plates are in metallic contact that the fluid between exists in a similar condition to a portion of a vibrating string cut in the centre of the adjoining vibration; having the nodal point in the centre where there is no action. Now, let us separate the connecting wires, when at once we transfer the polarising points to the ends of the wires, leaving the plates and electrolyte quite neutral.

As a further illustration of polarisation from only one polarising point, let us take a long narrow gutta-percha trough, having a copper bottom, to which a small piece of zinc is soldered at one end; on filling up the trough with water, slightly acidulated with sulphuric acid, at once an electric and chemical action is produced, the copper being electrically protected through the polarising of the zinc. Let us vary the experiment by dividing the trough in the centre with a solid diaphragm, filling each cell with acidulated water, in a short time it will be observable, that in the cell farthest from the zinc the copper is corroded by the acid as if no zinc were in contact, but in the other cell perfect protection is given; by substituting a porous diaphragm, complete protection is given to the whole plate, clearly showing that it is the fluid only that is polarised. If the trough is long in proportion to the size of the zinc, protection will not be extended to the extreme end of the copper, because of the induced positive action at that end, through the polarised state of the electrolyte.

We will now draw your attention for a few minutes to the nature of chemical action. Let us take two plates of platinum charging one of them positively; then immerse them face to face in acidulated water. No action will be observable; but bringing the unimmersed ends in contact, immediately chemical action is instituted in the electrolyte. We may vary the experiment by using a test-tube, inverted, having a platinum wire inside, supported by a perforated cork; let the tube be partially immersed in a solution of gold, rendered quite neutral with soda. No action will be observable; but on substituting hydrogen for atmospheric air, chemical action is at once set up, resulting in

a deposition of gold on the immersed end of the wire. It seems quite evident that the platinum wire has been deranged in its electrical quiescence through its polarisation: hence the chemical decomposition of the gold solution. And we may conclude that all chemical action is preceded by electrical derangement; for the disturbed state of the electrical equilibrium involves a disturbed state of the molecules of matter; as one disturbance does not occur without the other. We are, therefore, induced to accept this compound disturbance as chemical action. We may thus conclude that chemical action is the visible exhibition of electrical influences on bodies at insensible distances.

We may now make a few remarks on the nature of light and heat. It is recorded in the first book of the Scriptures that light was a distinct creation, consequently solar light is unique of its kind, all other lights requiring force in some way or other to bring them forth. Experience tells us that light generates heat in our atmosphere, and on the solid surface of our earth, as there is no direct evidence that heat rays emanate from the sun, but rather to the contrary; for, on ascending the highest mountains, we find a continued diminution of solar heat; on descending to the lowest valley, the reverse is the case. No doubt there is a cause for this, and may it not be accounted for by accepting the power of light in eliciting electricity in an allotropic condition in the form of heat? Many facts might be adduced to corroborate this view; but we will only allude to one at present. It is well known that the heat passing from the fire through the boiler plate enters into combination with the water, generating steam, in which it is said to become latent; but by a peculiar modification of the exit of the steam, this latent heat is transformed into positive electricity in enormous quantity.

By applying heat to a glass cup containing sulphur, when sufficiently cold (if separated), the sulphur will be found negatively electrical, and the glass will be positive; by using a metal cup the result will be reversed.

To show how easily the electrical quiescence of some bodies may be disturbed, let us take a mixture of phosphorus and any gum or saccharine matter, with a small portion of nitrate of potash made into a paste, having the temperature raised to what the hand can bear with ease, in the course of an hour or two there will be nothing left but the carbon and potash. Again, if we take a small portion of phosphorus oil and bisulphide of carbon, spread on paper, raising the temperature to about 90° to 95°, flame will instantly ensue.

Light—in passing through our atmosphere—produces a peculiar electrical condition; the oxygen showing itself in a state of electrical activity. If we take two bottles filled with atmospheric air from a dark room, having suspended from the stopper a piece of paper that has been previously moistened with the usual preparation of manganese, or with pyrogallic acid and potash, placing one bottle in the sun, after a time the paper in the sun will show strong indications of electrized oxygen or ozonized air, while the paper in the dark will exhibit little indications of changes. Light has great power in producing various changes in bodies both electrically and chemically; for instance, in upsetting the equilibrium of the two gases, chlorine and hydrogen, forming hydrochloric acid. Light again is found to be a powerful agent in decomposing the oxides of the perfect metals, such as the silver salts. The decomposition of nitric acid has long been known through the action of light being resolved into oxygen and nitrous acid. If we admit that light has power to derange the electrical quiescence of one or more elements in a compound, there can be little difficulty in comprehending that chemical action follows.

Having said all that I think will be requisite to base photographic action upon, I will at once proceed to apply these principles to an explanation of photographic phenomena.

The daguerreotype process being the first in use, and well adapted to simplify the application of the principle, I think it well to explain it first.

To produce a good daguerreotype picture it is requisite to have a plate well cleaned and polished, leaving it free from all impurities, exposing it to the vapour of iodine and bromine in proper proportions, and, after due exposure in the camera and development in the mercury-box, a perfect picture will be the result. Now in this routine all seems simple enough, excepting how the change has been produced from the action of the light in the camera, causing the silver to combine with mercury when the light has acted, and resisting it for a time where it has not done so. Though several surmises have been made from time to time as to the true cause, I believe it has fallen to my own lot to

explain that cause. Experience tells us that the more pure is the silver surface prior to exposure over the iodine and bromine the more perfect will be the finished result (the reason will be given afterwards). When the plate is coated we have a thin film of iodide and bromide of silver easily deranged by the action of light in its electric quiescence, the parts where the light has infringed being left in a positive condition, the other portions remaining perfectly neutral. When this plate is exposed to the action of vapour of mercury the electric tension existing polarises the vapour in contact to a limited distance; thus an attraction is set up, causing a combination of the two metals. As long as the polarising force is kept up the neutral parts of the plate are protected in zones proportional to the polarising force produced through the tension of the plate. When the induced positive parts of the plate are neutralised the protection at once ceases, and the mercury condenses mechanically over the whole surface. Any operator having practised with a small ring-lens on a two and a half inch plate must have seen the practical result of this theory of action. Under the best of circumstances condensation takes place towards the edges almost from the commencement of exposure to the vapour of mercury, thus showing that the small electrified surface in a state of tension in the centre does not yield the conservative power beyond a certain area. In very dull, damp weather, if the plates used are not perfectly pure in themselves, or badly cleaned, a good clear result cannot be obtained; but under such circumstances, after the plate has been cleaned in the ordinary way, then coated with any greasy body (those, of course, being good non-conductors are preferable), perfectly free from water, leaving just so much as will coat the organic and other matters in the pores of the silver surface; then giving the requisite amount of iodine and bromine, but exposing in the camera only for one-fourth to one-third of the time required in ordinary cases. Now, in developing, it will be found that it requires three or four times as long as is required for an ordinary plate to get sufficient mercury deposited to produce a vigorous picture.

Here we have two modes of preparing the plate, resulting in a great disparity of time requisite in the camera; this has generally been attributed to a greater degree of sensitiveness in the one case over the other; but, with all due deference, I beg to suggest a different solution of the matter. In the first case we have a plate often impure in itself with the addition of a portion of the cleaning matters used left in the pores of the plate, so that in the course of developing, local electric action is set up before the whole of the polarising power of the plate has been exhausted, rendering it necessary to check further exposure, else the blacks of the picture would become spotted with mercury. In the second case we have a plate, where all local action is prevented by rendering the whole surface nearly perfect as a non-conductor, permitting the whole tensile force to be exhausted in attracting the mercurial vapour.

As a further evidence of the truth of an electrically disturbed condition of the iodized surface, I may allude to the condition denominated solarisation: every operator knows that an excess of light produces a peculiar action on the prepared plate, causing such parts to unite with a very limited portion of mercury, whence a peculiar blue coloured amalgam is the result. Taking the electric principle as a guide, I believe we shall have little difficulty in solving this phase in daguerreotyping. In a thinly-coated plate the solarising point is soon arrived at: in a deeply-coated one—somewhat longer—so that thickness of the film of iodide of silver has something to do in the matter. Now if we admit that light acting on a prepared surface for a definite time, induces a positive condition to a certain depth—but if prolonged the whole thickness will be in a state of tension—hence the pure silver below becomes a defender of that electrical tension produced by the action of light, consequently on those portions of the plate that are over exposed by losing a great portion of their polarising power a smaller quantity of mercury is attracted.

To show that this is the correct view of the matter, insulate a plate in the camera-slide, charge the back of the plate positively with frictional electricity of a low degree of tension; after exposing a time that would usually solarise the plate, convey the slide to the mercury-box for the usual time, when it will be seen that no blueness exists, but a good solid white will be the result.

I might now go on to apply these principles to the unravelling of every little difficulty arising at times in the manipulatory processes; but as I think it would be superogatory on my part to do so, thinking every intelligent mind will be able to apply the principle himself.

In point of time the talbotype process comes next; but as the same leading principles are common to the albumen-waxed-paper and collodion processes, I need say little about the paper varieties, leaving the full examination for the collodion processes.

In the calotype processes we have an iodide of silver formed in the paper, serving the same purpose as that on the daguerreotype plate, namely, a negative quiescent surface easily deranged by the action of light from a negative to a positive condition, polarising the developing fluid while in a state of decomposition, thereby determining a deposition on the light-affected portions of the sheet.

The long-keeping qualities of sensitized waxed-paper proceeds from the pores of the paper being filled with pure wax (an excellent conductor), enveloping each fibre, thus doing away with the local action incurred where simple paper is used. Some paper sized with heterogeneous materials cannot be preserved for any time, nor can the developing be protracted sufficiently to make a clear strong picture.

Pyroxyline, whether prepared from cotton or flax fibre, when kept for a time, exhibits symptoms of decomposition by giving off the elements of nitric acid. When dissolved in ether, it seems to remain in a comparatively stable state; but when any of the alkaline iodides are added, chemical affinity is soon brought into play in proportion according to the alkali used, the metallic iodides having little attraction for the nitric element of the pyroxyline; but little decomposition ensues for a considerable time.

The ordinary routine of iodizing the collodion, spreading on the glass, sensitizing in the bath, exposing, developing, and fixing, I need not describe; but at once enter into the causes of the various changes produced in the film, tending to a perfect result. When a plate is coated and immersed for a time in the silver bath, the iodide of silver precipitated in the collodion film is in a very favourable condition to be excited by the electrical action of the light in the camera. On application of the developing fluid an electrolytic action is set up in the fluid, similar to the induced action previously explained in the mercurial development of the daguerreotype. The various changes produced in the development of a picture have generally been explained on chemical principles. But as I conceive the great principle desired is that upon which depends the production of all chemical action; for it seems to me that all chemical action is the result of a previous disturbed electrical equilibrium as shown previously.

Let us now take a more minute survey of a collodion picture. In the first place we have a sheet of glass, a neutral non-conductor, on which is spread a film of collodion (properly iodized); this collodion is likewise a non-conductor, the iodide and bromide of silver also having the same properties in a high degree. Here we have everything negatively quiescent, but on partial exposure and on flooding with a developer (such as gallic acid, pyrogallic acid, or sulphate of iron) at once a controlling action is set up by the electrified portions of the plate, determining a deposition of deoxidized silver on the light-affected parts; but, without an acid in the developer, it is scarcely possible to carry on the development without a fogged state intervening. The use of acid, I think, has not been clearly understood hitherto. It seems to me to be useful simply as a conductor of electricity; for, if we use any of the salts undecomposable by the developing agents being slightly on the acid side, perfect development will be the result.

It is well known that an old decomposed collodion tends to give brilliant, clean, hard pictures. Now, assuming that my idea as to the use of acid is correct, there will be little difficulty in comprehending the reason of this property of old collodion, or collodion holding a portion of iodine or bromine in a free state; for when the coated plate is immersed in the silver bath, iodide of silver and nitrate of potash (or other base) is formed in their definite proportions. The free iodine in the film will unite with its constituent portion of silver, leaving an equivalent of nitric acid free in the film just where it is wanted, for on pouring on the developer its conducting power is at once continued through the body of the film, checking any tendency to local action on the lower side of the film. That all the stains and dirtiness are upon the glass surface is easily provable; for by transferring a dirty picture to leather or prepared card, letting dry, then rubbing with cotton-wool, all the useless deposition will be cleared away, leaving a perfect and clean picture. Having said enough as to the practicability and utility of these views, I will conclude for the present, trusting you will pursue a course in accordance with them, and thereby develop the photographic art into a fixed science.

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held on the evening of Thursday, the 12th inst., in the City of London College. F. F. STATHAM, Esq., M.A., F.G.S., in the chair.

The minutes of a previous meeting having been read and confirmed,

Mr. G. WHARTON SIMPSON called attention to a couple of large photographs by M. Jeanrenaud, one of the ablest landscape photographers in France. They were worthy of examination, he remarked, for their excellence, but the especial object for which they had been forwarded by that artist was to illustrate the very great amount of angle he had been able to include with satisfactory definition by using Dallmeyer's No. 4 triple lens. M. Jeanrenaud had marked on the picture the amount of subject included by one of the best French landscape lenses of similar focus, which was about one-third of the picture less than was given with the triple. There was, moreover, considerable depth of definition. The photographs, which were from dry plates, by M. Puech's dry collodion, were very fine. Mr. Simpson also announced that the prints by Mr. A. Burns were now ready for distribution. He had written, asking Mr. Burns for a few particulars of his method of working in producing such views, in the form of a short paper for the Society. He would read the part of his letter referring to the subject, which was as follows;—

"With regard to a paper for the Society on obtaining cloud negatives and printing in skies, I fear I cannot do anything in that way. What little I do know on the subject is just what has appeared in the News and other journals, and a mere compilation by such an indifferent hand would not profitably occupy the time of the South London Photographic Society.

"The card picture is printed from a stereo negative obtained by the ordinary Fothergill process, very early (about 5 a.m.) one morning in June last, the exposure with a pair of Horne and Thornthwaite's small new lenses and smalls top, from beginning to end occupied 60 seconds, but the whole plate did not receive so much time, the lens being opened and closed *very slowly* by a shutter inside the camera, so that the immediate foreground would receive at least double the exposure of the distant castle &c. In this way I sometimes manage so as to obtain natural skies, and in the negative referred to, all the clouds present at the time may be seen in the negative, but too dense to print with the rest of the picture."

Mr. G. PRICE then read a paper on "The Theory of Positive Printing.—Albumenized Paper, and the Action of the Sensitizing Bath" (see p. 126 and p. 137). After which the Chairman, in moving a vote of thanks to Mr. Price for his very able paper on a subject of great interest and importance.

If the question were thoroughly examined, it opened a very considerable scope for inquiry. It was perhaps a matter for a little regret that any subject of personal antagonism had been introduced into the paper, and he would suggest that this part of the paper was scarcely suitable for discussion in a society's meeting. The subject presented ample field for discussion, however, and had been most comprehensively treated. There was first the general question, and then the distinctive propositions with which Mr. Price concluded his paper, which he (the Chairman) again read to bring them under the immediate attention of the meeting.

Mr. PRICE explained that the observations in his addendum were not intended for discussion. There was, however, neither personality nor antagonism intended. He had felt it important to clear the subject of certain mis-statements, and he had taken the advice of several unprejudiced persons and some friends of the *British Journal*, who all had concurred in the recommendation that they should be rebutted in this way. He had felt no antagonism, intended no personality, and only wished an important subject to be cleared from misleading statements, that the truth might be established.

Mr. SEBASTIAN DAVIS asked Mr. Price whether he had formed any opinion as to the constitution of the salts formed by weak solutions of nitrate of silver and albumen as compared with those formed by strong solutions. Did he regard them as differing in chemical character?

Mr. PRICE had, in his paper, simply referred to Messrs. Davanne and Girard's statements on the subject, in which they repeated a fact well known before.

Mr. DAVIS was not aware that it was known that a precipitate of different character was formed.

Mr. PRICE said they did not say that, neither did he; but, nevertheless, there must be a difference in the chemical constitution, or there could be no difference in the character of the precipitate.

Mr. DAVIS said the subject was a difficult and complex one, and considerable doubt existed as to the calculation of the equivalent of albumen, as it was necessary to multiply the different elements in order to state the proportion of sulphur and phosphorus.

Mr. MARTIN said that from analogical cases he would lead to the conviction that a definite chemical compound would be formed, whatever the strength of the solution—the difference in physical appearance, described by MM. Davanne and Girard, arising in his (Mr. Martin's) opinion solely from the variable state of agglomeration of the particles; that, in short, a definite compound of albumen and nitrate of silver was formed in each case, just as gelatinous alumina and pulverulent alumina—the one obtained from a cold solution and the other from a hot solution—were nevertheless both alumina.

Mr. PRICE held that all combinations below that which produced complete saturation were imperfect albuminates.

Mr. DAVIS asked what Mr. Price understood by imperfect albuminates.

Mr. PRICE said that by the term albuminate or perfect albuminate of silver he meant the highest or most complete combination, which produced what was termed complete coagulation. Combinations below that he would call imperfect albuminates.

After some further conversation on the subject,

Mr. HART thought that precipitates produced by weak or strong solutions were identical in constitution, albumen being a highly colloid substance, the more dense the solution the more firmly it held any salts of silver, so that a higher amount of silver was found in the dense precipitates than in the light precipitates.

Mr. PRICE asked Mr. Davis if he considered the albuminate of silver a combination of albumen with nitrate of silver, as a whole, or as a phosphate, carbonate, &c.

Mr. DAVIS was uncertain, but should say it combined as a whole.

Mr. HART had analysed the ashes of some albumenized papers after burning and found them to contain sulphide of silver.

Mr. DAVIS expressed surprise that Mr. Price should imagine that it was not generally known that the base of the chloride used, and the nature of the nitrates formed affected the tone of the print. The idea that they did affect the print had been held for years. He remembered that some years ago Mr. Heath brought the subject under the attention of the parent society.

Mr. PRICE said that so far as he had been able to ascertain the notion had not been commonly held. An article which appeared in the journal of the Photographic Society referred to that idea as having *recently* gained some attention. He knew that it had been held by some that barium affected the colour of the print, because of a combination between the albumen and the barium; but he had tried everywhere almost in London without being able to meet with albumenized paper salted with barium.

A conversational discussion arose on the question whether the action of the nitrates had been recognized, and upon the use of barium paper and the difficulty of obtaining it.

Mr. HARMAN thought chloride of ammonium was the best salting chloride; and the reason was, that the prints were always red in the pressure-frame, so that there was more control and certainty in toning them.

Mr. HOWARD thought that one of the advantages of ammonium arose from the fact that it was a ready solvent of salts of silver, and thus aided in producing even homogeneous film of silver on the albumenized paper, by the more ready assimilation as it were.

Mr. PRICE asked Mr. Harman if the redness in the pressure-frame was not rather due to the proportion of albuminate of silver than to the base of the chloride.

Mr. HARMAN said that some samples of albumenized paper would print black, no matter how much albumen there might be.

Mr. PRICE said that was a question of the proportion between the two; if the chloride were in greater proportion it would print dark.

A conversational discussion on this subject followed in which Mr. BLANCHARD mentioned the curious circumstance that a certain pair of negatives, printed on the same paper at the same time, in the same light, and with the same exposure, one gave a red print and the other a purple tint, the result always being the same.

Mr. HART had noticed that on mixing chloride of ammonium with albumen a decomposition took place, in which ammoniacal gas was given off. The chlorine either combined with some base in the albumen or with the albumen itself. The prints on such paper were probably redder because there was a less amount of base. He had printed two pictures which he would then show—one on normal albumen, the other on albumen with chloride of ammonium. When the ammonium paper was fully printed the albumen paper only showed signs of appearing; in fact, it took three times as long as the other to print. In toning the ammonium print occupied twelve minutes and the albumen sixteen minutes. The albumen alone never got deeper in the pressure frame than a salmon colour. Regarding coagulation, he had some experiments in progress which would he hoped throw light upon it. If the albumen combined with the silver, what became of the nitric acid liberated? That would act very specifically on the albumen, for it was well known that nitric acid was the most powerful test for albumen, a five thousandth part being sufficient to produce insolubility.

Mr. WHARTON SIMPSON said that one important element in giving this specific colour to the print in the pressure frame had not been noticed. He referred to the kind of light in which they were exposed. Most photographers would have observed, that paper which, exposed to soft diffused light, printed with a blue or purple tint, when exposed to sunlight assumed a red tint. He had recently carried the matter further, and but for the pressure of more immediate duties, he would have completed experiments to the present meeting. He found, when submitting a piece of sensitive paper to the concentrated light of a lens, that a still different tint was produced, so that three distinct tones were produced on one piece of paper, the difference caused by light alone. At one end of a piece of paper, placed at the focus of a lens in sunlight, the tint produced very rapidly was of an orange tint, and that produced, it was very slow to go beyond it; direct sunlight gave a reddish brown, and diffused light a purple. These distinctive differences were less marked after toning and fixing, but they still remained the same in character.

Mr. HARMAN and Mr. HART confirmed the view that the character of the light largely influenced the colour.

Mr. HOWARD suggested that heat might have something to do with the colour.

After some further conversation, Mr. HARMAN, referring to Mr. PRICE's summary of questions said, that he found vigour to depend largely on the use of a strong solution and short floating, the prints were produced by shorter exposures, and were more brilliant.

Mr. PRICE asked if in such case he found it necessary to print deeper, or if the prints lost more in toning and fixing than with a weaker bath.

Mr. HARMAN did not find any deeper printing necessary.

This view was confirmed by Mr. DAVIS and Mr. LEAKE.

Mr. T. R. WILLIAMS quite agreed with the remarks of Mr. Harman, especially as to the advantage of prints appearing red in the pressure frame. A great advantage was the possibility then of seeing exactly the amount of toning effected, which was very difficult where the print was blue to begin with. Regarding the use of barium, he felt assured of its advantage, and had used five grains of barium and five grains of ammonium for many years. There appeared to him considerable misapprehension to exist regarding the necessity, under all circumstances, for over-printing. In his establishment they scarcely printed any deeper than was required in the finished print. This, through the experiments of Mr. Cooper, they had discovered to depend upon the use of distilled or rain water for washing before toning, as, when common water was used, deeper printing was necessary.

Mr. LEAKE referred to a recent trial he had made of some paper which was albumenized without any chloride. It gave flat, poor, meagre prints. He had recommended the maker to use 10 grains of chloride of ammonium, which was attended with a great improvement in the prints. He thought it a pity that manufacturers of albumenized paper would not state the proportion and nature of the salt used in salting the paper, as at present they were obliged to proceed very much on the

principle of putting a lump into a tolerable sized jug. The system of printing was exceedingly empirical. All papers were treated alike both as to silver bath and toning, and no distinction was made as a rule between the requirements of feeble or vigorous negatives.

Mr. SIMPSON said, Mr. Leake's experience with paper simply albumenized was somewhat at variance with general experience, as excess of vigour and lack of half-tone, was the general result of such paper, as indeed the examples exhibited by Mr. Hart illustrated.

Mr. HART said, in his experience it was almost impossible to get anything but black and white, without half-tone with such paper.

Mr. HARMAN had always found the smaller the proportion of chloride, the slower the printing, and the more brilliant the print.

Mr. DAVIS remarked, in reference to the loss in toning and fixing, when common water was used for washing, that he had prepared a piece of plain paper by floating on nitrate of silver; and obtaining a blue print in the pressure-frame had immersed in chloride of sodium previous to toning, which caused it to assume a bright red colour, showing the reaction of nitrate of silver and chloride of sodium in the print.

Mr. HART had directed attention to the advantages derivable from the use of soft water in a letter to the PHOTOGRAPHIC NEWS three years ago. He had been in the midst of some serious toning troubles, which the use of a softer water for washing at once relieved him from.

After some further conversation,

Mr. SIMPSON moved the adjournment of the discussion, as it was now late, and the subject was not exhausted. This was agreed to, and it was announced that Mr. Harmer would also read a paper "On Mask Printing," and Mr. Cooper a brief communication "On Substitutes for Albumen." After a vote of thanks to the Chairman, the meeting was then adjourned.

Photographic Notes and Queries.

WORKING HOURS OF PHOTOGRAPHERS.

MY DEAR SIR,—In your last Number I saw, in the "Answers to Correspondents," an allusion to some complaints emanating from the employés of a photographic establishment at Notting Hill.

As I know of no other business of that kind in the neighbourhood than my own, I, in justice to myself, beg to offer you the other side of the question. In the first place, no one in my employ has worked more than seven hours and a half this winter and during short days and foggy weather. I will leave you to judge how much of that time could be profitably employed.

As the longer days are now coming in I desired the men to work nine hours per day and the boys nine hours and a half. All time beyond that I have always paid for, both to men and boys.

A notion seems to have entered their heads that they should work the same hours only as operators employed in the close confinement of the dark room, and at that requiring infinitely more head work than printing, divided, as it is, into different branches, each one to his own department.

Several of my hands I could have well dispensed with, but having had their services through the summer, I have kept them through the winter, and at full wages too.

During this winter I have paid a lad to be here two hours before the others to get the workshops dry and warm, ready for the day's operations.

I now, sir, leave you to judge how tyrannical has been my conduct.

Apologising for thus troubling you, I remain, dear sir, yours obediently,

W. ENGLAND.

P.S.—Since writing the above I have discovered the chief mover in the affair to be an apprentice in the house, of whose character the best I can say (after an experience of five years) is that it is very difficult to get him out of bed before 9 o'clock in the morning.

Photographs Registered during the Past Week.

Talk in the Studio.

MR. MEAGHER'S CAMERA.—The handsome large trunk camera sent by Mr. Meagher to the exhibition of the Photographic Society to be sold on behalf of the Lancashire Fund not having there met with a purchaser, it is now proposed to dispose of it by subscription sale. One hundred shares at five shillings each make the price of the camera; each subscription of that amount entitling the subscriber to one chance in the drawing. Applications for shares should be made to Dr. Diamond, Secretary to the Photographic Society, Twickenham House, Twickenham. The camera is a very perfect one, and well worth the money for a chance.

THE BEST SIDE OF THE FACE FOR PORTRAITURE.—A Correspondent says: There is a point in portraiture that I have never seen hinted at in any photographic publication: it is, that everybody has *two sides* to his face. I might state it less equivocally, however, by saying that the sides of the face are not symmetrical, and you may notice that almost everyone has a better look on one side than on the other. This difference between the sides of the face is much more remarkable in some persons than in others, but in all it may be seen in a certain degree. The nose is always more or less turned to either side, commonly the left, and will consequently alter the expression by rendering one side of the face wider than the other. This point is of considerable importance to portraitists, as they should always take the *best side* of their sitters.

To Correspondents.

COLOURED GLASS.—"A. E. II" sends a sample of glass, which is perfectly satisfactory and non-actinic. The samples sent by "A Man in the Country" are rather of a light brown tint than orange, and are quite unsuited for the dark-room.

A.—Streaks on the plate in the direction of the dip will arise from several causes; but those to which you refer, as appearing generally when fresh silver solution has been added to fill up the bath, probably arise from some floating matter at the surface of the solution, which has accumulated from the sides of the bath; in such case cleaning the surface will frequently remove the streaks. Giving the plate a lateral motion in the bath will often prevent the formation of streaks. The addition of a little nitric acid is often a remedy. Sometimes after taking a few plates it will disappear without further steps.

DR. LANGUE.—We do not know whether any one in this country is agent for M. Berth's camera. 2. From the results we have seen produced it appears good, but we do not know anything of it beyond this.

W. B.—We have no means of accounting certainly for the stain on your print; it appears to have resulted from the action of an acid. 2. It is well to wash thoroughly before toning; two changes of distilled water, if properly manipulated, might be made to remove the greater part of the free nitrate.

D. FERGUSON.—The process referred to is worked by the American Photo-type Company, and, we presume, they are the patentees of the process.

AMARANTH.—The intrinsic value of a 12 by 10 photograph, apart from its value as a picture, may easily be estimated by ascertaining the trade price for printing such photographs, which is about 18s. per dozen. 2. The selling price of photographs of that size varies from 5s. to 10s. and upwards, according to the excellence of the picture and the interest or rarity of the subject. 3. We cannot recommend you a publisher. 4. If you merely wish to make photography pay its own expenses, and have some good negatives, the Amateur Photographic Association will afford you the best facilities for disposing of prints. 5. Reproductions are rarely so valuable as photographs from nature, unless the originals are rare and valuable. 6. There is no reason why a good negative should not be taken on flatted crown. For large plates it is apt to break, and its surface is not quite so good as patent plate. 7. Flatted crown is generally slightly curved, and is not polished like patent plate. The latter is by no means always of one uniform thickness, nor is it always quite free from blemishes; but if of good quality it is tolerably free. The price depends upon the size of the plates; 12 by 10 plates are about 2s. a foot; 8½ by 6½ plates are about 7s. a dozen; but prices vary.

AMATEUR IN ST. THOMAS, W. J.—An ordinary copying camera and suitable lens, say the triple, will answer every purpose for copying oil paintings. We are not aware that any camera has been made for that work only. 2. Unless instructions to the contrary are given we apprehend that the rose tinted albumenized paper should be treated in all respects as that without a tint. See first article in the present number. We are obliged by your kind offer of services in the West Indies.

F. G.—Various substitutes for yellow glass have been tried with more or less of efficiency. Your proposition to use coloured gelatine may probably answer. It is easy to colour it, but it is doubtful whether the colour will be quite non-actinic or permanent. A solution of annatto or saffron will give you a good deep yellow; but these will be apt to fade in sunlight. The addition of a grain of nitrate of silver to each ounce of gelatine solution will, when exposed to light, probably give you a permanent non-actinic colour. Judson's orange dye will probably answer. Coating the plate with plain gelatine, and when nearly dry immersing it in a solution of the colouring matter will probably be a good mode of applying it.

Tnos.—The camera to which you refer being a modern invention is less likely to be obtained second hand than one of older form. We are not very familiar, however, with the class of photographic materials to be obtained second hand; but there are, no doubt, sometimes bargains to be had. The price you quote for the camera referred to is, if we remember

rightly, for a complete equipment of double hacks, leather case, tripod, &c. If you require the camera alone the price would probably be less.

PHOTOGRAPHIC ENTHUSIAST.—A Stanhope lens is a cylindrical piece of glass with both ends convex, of such curves as will make the foci of parallel rays refracted at one surface coincide with the other, so that objects placed in contact with one surface are seen greatly magnified on looking through the other. 2. The Coddington lens is a small spherical lens, with the equatorial portions ground away so as to correct spherical aberrations. Neither of these are suitable for photographic purposes. 3. A movable partition in a belows stereoscopic camera need only come in contact with the edges of the folds, it is not necessary to fit into the gussets. It may be of any convenient material. 4. Some operators use a leather for polishing glasses, just in the condition it is sold; but it is safer to wash it thoroughly in spirits of wine and water. 5. A bromo-iodized collodion will bear a stronger iron developer than a simply iodized sample. 6. In the panoramic pictures exhibited at the London Society, the lens had no part in producing the panoramic results. It was simply a common achromatic stereoscopic lens, and the picture might have been better had the lens defined better. The panoramic result was due to a mechanical contrivance for moving plate and camera in proper ratio during exposure. The specification will be shortly published. 7. It is probable that it would cost you more to make a bad lens than to purchase a good one; even with the best written instructions to guide you. Purchase a good lens if you can; but, at the same time, do not be discouraged if you can only afford a cheap one. By great care and skill good results have been produced by a common single lens.

M. B. L.—By mixing a portion of a toning bath with your silver bath you have simply precipitated a portion of the silver as a chloride, carbonate, acetate, &c., the exact character of the precipitate depending on the constitution of the toning bath. All you can do is to remove the precipitate and recover the silver by reducing it. Then test the clear solution, and ascertain to what extent it is weakened; sufficient nitrate of silver should then be added to make up the proper strength again. 2. A bath which has been used for exciting collodion plates does not give brilliant results when used for paper. In any case you should get rid of as much of the iodide as possible by precipitation, as recommended by Mr. Hardwich; that is, adding a few drops of a solution of citric acid, which, forming a precipitate of citrate of silver, will carry down some of the iodide of silver.

A. R.—A mixture of bichromate of potash and gelatine, when exposed under a transparent positive, and then soaked in water, will give an image in relief; from a gutta-percha mould of which an electrolyte taken would present a block, the raised parts of which would print the blacks of the picture. The property possessed by gelatine, or similar substances, in combination with bichromates, of being rendered insoluble by light, is the germ of the greater part of the heliographic processes. In the process referred to, the parts acted upon by light are insoluble, and are not, therefore, affected by water; whilst the parts not affected by light retain the ordinary property of gelatine when soaked in water, which is, of course, to swell up.

D. W.—The formula and manipulations referred to are, as stated, those of Mr. England. When he states that development is to be effected with "the usual three-grain pyrogallic acid solution," we presume him to mean three grains of pyrogallic acid to an ounce of water, with the usual amount of acetic acid, or citric acid, and a few drops of silver solution.

BRADFORD.—Dr. Hill Norris's plates are generally developed with pyrogallic acid; but if, as you state, you exposed one under a negative for a minute without obtaining a trace of an image on development with iron, it is probable you omitted to add any silver solution to the iron, in which case you would not, of course, obtain an image. An exposure of a minute to daylight should be much too long. As you describe your operations, they are correct; but we presume you neglected to add silver to your developer—an omission which persons unaccustomed to dry plates not unfrequently make. You will find many articles on producing transparencies in our back volumes; we may especially mention one on page 410 of the 6th volume.

A LONDON AMATEUR.—Our opinion coincides with your own as to B. 2. We should recommend B 1, as satisfactorily combining both the capabilities you require. 3. With A 3 you must have stereoscopic lenses as well. 4. So far as our experience goes, the B are in all respects at least quite equal to A.

THOMAS JONES.—Messrs. Marion and Co., of Soho Square, publish original portraits of the Prince and Princess of Wales and of some other members of the Royal Family.

GOOD NIGHT.—We are very highly gratified with your specimens as illustrations of the value of the information referred to. Some of them are very perfect indeed, and equal to those produced by professional photographers of high standing, and all exhibit very careful and intelligent manipulation, and much good taste. We have little to criticise in them or suggest for their improvement. Your lens is, as you doubtless are aware, not quite equal to producing male standing figures. Take care to keep your accessories quiet and subdued, and the same with pictorial backgrounds, suggestion rather than definite making out, is all that is required in each. Many of your pictures are very good in this respect, but some are scarcely so quiet as might be desirable. If you continue to progress in the direction you have done, your work will be inferior to none; it is now superior to much with more pretension. Regarding the rapidity of lenses, the rule is, other things being equal, that the larger the aperture in relation to focal length, the quicker the action, therefore the latter of the two to which you refer would be quickest, and give the best results. Both by the maker you name, are, however, good. If you have length of room, and can afford it, we should recommend the larger one. The salaries of operators in London vary very much. We should say they range from two guineas to five guineas a week, depending on the ability of the operator and the character of the establishment. We shall be glad to hear further from you.

YOUNG PHOTO.—Your specimens arrived so much broken that we could make very little of them. So far as we can judge the fault is simply under exposure. No. 1. appears to be a fogged plate from using a bath in bad condition. Possibly a little nitric acid would remedy that. If not, add carbonate of soda and sun the bath. The other two plates appeared both to be very much under-exposed. It is difficult to say how late in the day you may produce pictures; generally, any time up to sun set, but requiring very long exposures, as the sun is declining. A few lessons from any capable professional photographer would help you very much, but we cannot recommend any one in these columns. A low temperature in the operating room generally makes operating altogether slower.

Several correspondents in our next.

M. MEYNIER'S NEW FIXING SALT.

THE application to photography of a salt which might replace hyposulphite of soda and cyanide of potassium, for fixing either negatives or positives, without presenting the inconveniences peculiar to these two substances, was an event too important to the photographic art, and for the permanency of pictures obtained by the aid of salts of silver, not to strongly excite the attention of all who are interested in the progress of science and who regret seeing so many excellent proofs rapidly fade.

The Marseilles Photographic Society, of which M. Meynier is an active member have submitted the new fixing agent to the necessary tests in order to prove its superiority over hyposulphite of soda, and M. Teisseire has made a report upon it, of which we give the substance as recorded in the *Moniteur de la Photographie*. The results are less satisfactory than could have been desired. We hope shortly to record the results of our own experiments in the matter.

The salt proposed by M. Meynier is the sulpho-cyanhydrate of ammonium, which he obtains by mixing the compound of sulphide of ammonium dissolved in water in presence of a porous body, such as sawdust.

Chemistry offers several other methods of preparing this salt. Its elements are, as its name indicates, sulphur, hydrocyanic acid and ammonium. It presents, therefore, some analogy, by its elements, with the three fixing agents hitherto employed in photography—hyposulphite of soda, cyanide of potassium, and ammonia.

Like them, it possesses the property of completely dissolving the chloride, iodide, and bromide of silver, and all identical compounds, and particularly, according to M. Meynier, the sulpho-cyanide of silver which may be formed during the fixing of proofs. M. Meynier states that the new salt is not poisonous like the cyanide of potassium. These properties induced him to employ it for fixing negatives and positives.

The sulpho-cyanhydrate of ammonium dissolves the argentine compounds employed in photography very readily, and its most remarkable property with respect to the permanency of the pictures is, that notwithstanding the presence of sulphur among its elements, it does not precipitate that element under the action of acids, which is the primary cause of the fading of proofs fixed with hyposulphite of soda.

To verify this property a saturated solution of hyposulphite of soda was placed in one test glass, and a saturated solution of sulpho-cyanhydrate of ammonium in another. A drop of acid added to the solution of hyposulphite of soda caused an abundant white precipitate of sulphur. The solution of sulpho-cyanhydrate of ammonium similarly treated, on the contrary, remained limpid. This limpidity was not changed under the action of a very strong proportion of acid. The liquid only became feebly coloured yellow red. From these facts it evidently results that the sulpho-cyanhydrate of ammonium does not precipitate sulphur under the influence of acids, and admitting that some sulphur

must be liberated, soluble compounds only are formed, which will be removed by washing, and leave no sulphur in the substance of the paper.

The next experiment was to ascertain whether the new fixing salt could be applied indifferently to albumenized, and to simply salted paper; the results were stated as follows:—

1st. *Salted paper*.—We believe the new salt to be perfectly applicable to proofs on salted paper, sensitized either in the bath of 15 per cent. of nitrate, or of 5 per cent. of ammoniacal nitrate. The faces come well out without losing much vigour in the fixing. The proof remains perfectly pure in the whites, without taking a yellow tint. (N.B. During the fixing, the following phenomenon takes place: after a few minutes' immersion in the sulpho-cyanhydrate of ammonium bath, the proof becomes covered with a white veil, which is formed by sulpho-cyanide of silver. This veil ultimately disappears, especially if the proof is passed to another new bath, when the picture soon resumes all its vigour).

2nd. *Albumenized paper sensitized in an ammoniacal nitrate bath*.—We have not obtained good results by fixing proofs upon ammoniacal paper, by means of sulpho-cyanhydrate of ammonium. The ammoniacal nitrate solution itself removes some albumen from the paper, and consequently its gloss; the sulpho-cyanhydrate finishes the work, and but very little albumen remains on the proof. The colour given by the toning disappears, and the picture assumes a tint resembling that of proofs fixed in hyposulphite of soda and not toned. The albumen having for the most part disappeared, the pictures have very disagreeable dull tones, with no depth, and the whites become very yellow.

3rd. *Albumenized paper sensitized on an ordinary nitrate bath of 15 to 20 per cent.*—The sulpho-cyanhydrate might be employed to fix proofs on paper with 15 to 20 per cent. of nitrate, if we could prevent the paper turning yellow under its influence. The albumen remains intact. The tones given by the toning bath are well preserved if we take care to force them a little. The picture appears perfectly clear when viewed by transmitted light, but notwithstanding the most careful washing, it becomes yellow when dry. The question arises, Is this effect caused by the presence of sulphur in the elements of the new fixing salt, or by the albumen itself? But the fact is undoubted. We have, in presence of M. Meynier, made comparative experiments with hyposulphite of soda, and the new salt. Some stereoscopic pictures were cut in two, and one half fixed in hyposulphite of soda, and the other half in sulpho-cyanhydrate of ammonium; in the first, the whites remained pure, in the second, they yellowed considerably. Experiments made upon various qualities of paper, gave similar results.

With respect to the permanency of the proofs obtained by this process, time alone can show, if they be more durable than those fixed by hyposulphite of soda.

In conclusion, we think that the sulpho-cyanhydrate of ammonium may be employed in photography for fixing collodion negatives and positives upon salted paper, but that it

cannot be advantageously substituted for hyposulphite of soda, for fixing proofs upon albumenized paper, until we find means of avoiding the yellow hue it communicates to these papers.

We have not examined whether the new salt be poisonous or not. M. Meynier affirms that it is not.

SECRET FORMULÆ.

BY COLEMAN SELLERS.*

MR. PRESIDENT, I beg your attention for a few minutes this evening in reference to a matter which may serve as an illustration of one of the uses of photographic societies in general, and at the same time prevent some of those now present spending money needlessly.

There have always been persons who make a business of selling wonderful formulæ; in many cases they charge pretty well for their information, and in my own experience the ones thus trading are not always the originators of the processes vended. But to the point. I have in my possession a circular issued by a respectable house in New York, calling attention to a pamphlet which they offer for sale for the moderate sum of three dollars, and which is said to describe "a new process of photographic printing by which from 25 to 30 grains of silver will produce better results than were obtained by using 80 to 120 grains to the ounce of solution," and detailing many advantages as to keeping qualities, &c. Now this pamphlet, when received, is found to describe what (to use their own words) "may be called the fuming process, and consists in part in applying the fumes of ammonia to the paper after it is silvered, instead of using ammonia in solution with the silver, thereby increasing the sensibility of the paper without injuring the albumen surface." It then gives the proportion of silver solution thus:—

Water	1 ounce
Nitrate of silver	25 to 30 grains	
Nitrate of ammonia	3 grains.	

"Float the paper on this solution from three to five minutes, then hang up to dry by one corner. When it is dry it assumes a cone-like shape, and will keep in a dark room several days. When wanted to use place it in a box described in the drawing. Close the door and remove the stopple from the ammonia bottle, and allow the fumes to pass to the paper for five minutes. Then put in the stopple, and open the large door which will allow the fumes to pass off. The paper may be removed as wanted for use."

Now all this is very well. It is without exception one of the very best means of sensitizing albumen paper; and doubtless it is cheap at three dollars. But if it had been published in any of the public journals which we were in the habit of reading, and we had thus become possessed of the information in advance, we would all object to paying the three dollars. And, what is more, we would question the right of any party to make capital out of this public property.

In the last volume of *The American Journal of Photography*, Mr. Seely described the fuming process, and his article was copied abroad, even translated into French, and yet it did not attract one half the attention its importance demanded; as far as I can learn few persons availing themselves of it, and that mainly because its importance was not dwelt upon by the writer. The firm of E. and H. T. Anthony had been practising the method for several years, and Mr. Henry T. Anthony claims to have been the originator of it, as applied to albumen paper. While a Mr. Campbell four years ago published the process for plain paper in Vol. I., *American Journal*.

Now regarding the twenty-five to thirty grains bath. At the meeting of the Photographic Society of Marseilles, France, held on the 28th of February, 1862, "M. Terris described to the society a sensitizing bath which he used for albumen paper. To a bath of nitrate of silver of twenty-five grains to the ounce he added a certain quantity of nitrate of ammonia, which he alleged to preserve the albumen on the surface of the paper, and asserted that his toning was good even with so weak a bath as indicated, in proof of which he exhibited a set of beautiful cartes de visite." This was published in the English journals, and could have been seen by any one who was in the habit of reading the papers. It attracted my attention from

having, previously to the receipt of it, written on the ammonia-nitrate of silver for albumen paper, and stated that it was more properly a solution of oxide of silver in nitrate of ammonia, as had been clearly stated by Mr. Hardwich.

In my letter to the *British Journal of Photography*, dated April 28, 1862, writing on the same subject, I said "from careful inquiry as to the exact condition of various baths used here of this kind, I think I am safe in saying that, if a solution of nitrate of sixty or eighty grains to the ounce be made, and to this a solution of nitrate of ammonia be added, taking care to keep the solution very slightly alkaline, the exact equivalent to these so-called ammonia nitrate solutions will be produced. In no single case have I seen baths of this kind become discoloured from use, and what is remarkable, the range of strength for good work is very much increased. At my suggestion, and in order to test the matter for the information of your readers, I requested an operator here to make up a new bath, eighty grains to the ounce, and to use it from day to day without adding any more silver to it until his prints began to show the want of silver. He worked the solution down too low for successful floating, and still the prints showed no symptoms of meanness. The solution at this time showed by the hydrometer thirty grains to the ounce, and I cannot say how much longer it might have been used to advantage."

Any solution of nitrate of silver to which ammonia and nitric acid have been added, as was the case in all the so-called ammonia-nitrate solutions, were to all intents and purposes the same as what is now described in the pamphlet above mentioned—as they were all nitrate of silver and nitrate of ammonia in water—and were made alkaline to produce the effect which is now better obtained by the fuming. Paper floated on a neutral or slightly acid bath will keep white several days, and the alkalinity needed to produce good prints can be imparted to it by fuming to a greater degree without injury to the surface.

What is now sold for the three dollars is what has been written about in the public journals, and has been the property of the public for a long time. I myself have been using a bath with nitrate of ammonia in it for nearly two years, and have been fuming with ammonia ever since last spring, when I received the process from Mr. Henry T. Anthony, who showed me how they used the fuming in their own establishment. It had been my intention to show a few experiments this evening, in illustration of the chemistry of the process, but will content myself with merely stating that nitrate of silver is an oxide of silver combined with nitric acid, and that oxide of silver is soluble in ammonia, or in nitrate of ammonia; it is held more feebly in combination than in nitric acid, and hence will part with its silver to the chloride in the paper more readily than if combined with nitric acid, and the more alkaline is the solution which eventually dries on the film or paper, the more readily is it reduced by light. The solution in ammonia alone is inadmissible on account of the inevitable destruction of the albumen surface, hence nitrate of ammonia, as a neutral salt is better, and the alkalinity can be given by the fuming after the paper is dry. The consumption of silver is the same whether you use 30 grains to the ounce or 120 grains so far as the conversion of the chloride is concerned, but there is some economy in using a weak solution in as much as the liquid on the surface and which dries on also impregnating the paper to some extent is not so rich in silver, and it is probable that the large amount of silver is not advantageous to the production of good pictures.

In conclusion let me express the hope that the members of our infant society will be at all times ready to impart information; for while they are thus advancing the art, they will find that by giving freely they will the more freely receive, and thus in harmony defend themselves from imposition.

ON THE INFLUENCE OF IODIDES AND BROMIDES IN COLLODION, AND ON THE INFLUENCE OF DEVELOPING AGENTS UPON SHORT OR LONG EXPOSURE.

BY M. OMMEGANCK.*

BROMINE was introduced into the daguerrotype process as an accelerating agent, it caused much astonishment when, subsequently, the bromides were said to retard the luminous impression on collodion plates. This diversity of appre-

* Read before the Photographic Society of Philadelphia.

* Continuation of an Article on p. 41, vol. vii.

ciation had its origin in an imperfect method of experimenting. The circumstances were not all taken into consideration. It would not be difficult to demonstrate the causes, but such a discussion, to be complete, would divert us from the object we have now in view, and exceed the limits of an ordinary article. The accelerating action of the bromides in collodion, is unquestionably admitted.

We have established the principle (in our preceding article), that the greater or lesser sensitiveness of iodide of silver depends upon the abnormal dilatation which affects this salt at the moment of its formation in the texture of the collodion, and we have placed it in that category of aggregations, which, in chemistry, is termed the nascent state. Every re-agent which favours this state, and prevents the return of the iodide of silver to the natural contracted state, will be an accelerating agent. It will be much better adapted to produce this effect, if it be itself sensitive to light, and susceptible of being formed in the nascent state. Bromine realizes these conditions perfectly. If we consider that in a bromo-iodized collodion, the iodides and bromides are intimately mixed at the moment of their immersion in the silver bath, by the side of a molecule of iodide of silver (I Ag) is formed a molecule of the bromide of the same metal (Br Ag); perhaps even a double salt is formed; their alternate interposition must necessarily injure and diminish the force of attraction, which tends to bring them to the natural state in nearly the same manner as carbon acts upon the iron of tempered steel; not only does the dilation subsist longer in a compound of I Ag + Br Ag, but the interstices between their molecules, which are of two different forms, are wider, the luminous agent insinuates itself more easily into their medium, and the long and slow vibrations penetrate as well as the more rapid and short ones. As to the more considerable space which we suppose to exist between the atoms I and Ag, and Br and Ag, than between their combinations I Ag and Br Ag, we observe something analogous in the chemical compounds, which are explosive or easily decomposable, inasmuch as the atoms of these bodies are aggregated, contrary to the laws of their natural attraction, and in such manner, as to present a very considerable volume. Experiment has confirmed these theories with regard to photographic operations, for a collodion with equal parts of iodide and bromide is, in general, the most sensitive of any for instantaneous proofs; and, on the other hand, a strong dose of bromide is also necessary to allow of a long exposure.

There exists a great diversity of opinion on the state and kind of re-agents adapted to obtain the best result, as well for ordinary proofs as for instantaneous ones; we believe we may succeed by different methods, and that, above all, proper manipulation is indispensable. Nevertheless, some re-agents are preferable to others. This question seems to be very far from decided, inasmuch as the mode of operating by many distinguished operators is still a secret.

A series of questions which every photographer must frequently put, is the following:—

To which iodides and bromides must preference be given in the preparation of collodion? and must the collodion be colourless, or contain free iodine?

What is the best developing agent, pyrogallie acid or sulphate of iron? Must we acidulate the developing solution with acetic acid, citric acid, formic acid, or nitric acid?

Some of these questions appear to be solved, others still require a long series of experiments.

It is impossible to treat them all within the restricted limits of this essay: we must, for the present, examine the composition of the developer especially.

As the basis of the developing solution, sulphate of iron generally appears to merit the preference, except, perhaps, with dry collodion, where the use of pyrogallie acid is prescribed.

For ordinary productions we employ a bath composed as follows:—

Water	100	parts
Sulphate of iron	3 to 5	"
Glacial acetic acid	1½	"
Alcohol	4	"

For instantaneous pictures we reduce the quantity of acetic acid as much as possible, until we reach the limits at which a fogged picture results: the quantity must be determined at the time, and cannot be subjected to fixed rules. Two solutions are prepared, one of the strength of 1 to 100, the other of 1 to 1,000, and a mixture of the two in suitable proportions employed.

The employment of nitric acid, in lieu of acetic acid, may present many great advantages, especially for instantaneous pictures: it gives greater rapidity.

The employment of formic acid exhibits some remarkable peculiarities. Associated with pyrogallie acid in Mr. Claudet's formula, it greatly accelerates; but, on the other hand, it has the disadvantage of the reactions of pyrogallie acid upon the sulphate of iron. One among other results which its employment yields us in a bath of sulphate of iron of 3 per cent. is, that of fogging the picture completely, if used the same day it is prepared; two days subsequently it yields a good negative in the fraction of a second; eight days after its preparation it has little or no effect, even after an exposure of five seconds. A solution prepared with equal parts of acetic acid and formic acid acts very well the first day, but is rapidly decomposed in contact by sulphate of iron and the oxygen of the atmosphere; it becomes brown only after the nearly complete oxydation of the formic acid.

We do not specify the proportions for formic acid, or for nitric acid, because, as these acids are always diluted with a very variable quantity of water, it is necessary to have recourse to an acidimetric operation in order to ascertain their real value. In taking the sulphate of iron bath, given above as the starting point, we substitute for the acetic acid an equivalent quantity of some other acid. Take two drachms of acetic acid and colour it light red by means of some drops of tincture of litmus, then take an aqueous solution of caustic soda or potassa, and, by means of a graduated measure, put into the acetic acid the exact quantity of alkaline solution necessary to turn the litmus colour to a blue, noting the number of minims employed, and perform the same operation with the formic and the nitric acids; the three numbers found indicate the relative strength of the acids tested. Suppose that five drachms of acetic acid have been neutralized by ten drachms of the alkaline solution; that the nitric acid has required eight, and the formic acid four; then, in the preceding formula, we must replace the 1½ drachms of acetic acid by about 2 of nitric acid, and 4 of formic acid, to have the chemical equivalent. Finally, in taking two or three negatives, we must endeavour to reduce, as much as possible, the quantity of nitric and formic acids, according to circumstances, such as light, heat, state of collodion, silver bath, &c., the effect obtained can alone determine the quantity.

The employment of nitrous, and of acetic ethers, to replace the acids in the iron solutions, may yield excellent results; but it is a most delicate operation: the transformation of a portion of sulphate of iron into acetate or nitrate of iron, by means of the acetate or nitrate of baryta or of lead, may possess certain advantages. Our own experience has not yet given a very decided conviction on this subject.

A SHORT LESSON IN PHOTOGRAPHY.—No. 10.*

THE rules already given for taking an ambrotype are nearly all valid in reference to preparing a negative. The same collodion and the same sort of glass can be employed in both cases. The only differences in the preparation are referable to the time required for the solar impression, to the mode of development, and to the intensifying of the negative.

Time required for the solar impression.—In the negative

* From *Humphrey's Journal*.

it is as absolutely necessary to preserve the same grade of contrast between the lights, middle tones, and shades as in the ambrotype.

It is equally necessary to avoid all fogginess—to preserve the picture as bright and transparent in those parts which are to be transparent as can possibly be effected.

But these are the exact properties of the ambrotype; and now we arrive at that which is distinctly different. If you hold an ambrotype to the light and look through the glass you will easily distinguish objects; you will, in fact, be able to read through the darkest parts, through those parts on which the light has made the greatest impression; whereas, by holding a *correct* negative in the same way, you will not be able to distinguish a single letter through the darkest shade. And the same gradation of opacity is observable in the middle tones and the lights. This is the only difference that exists between a good negative and an ambrotype, and I must consequently impress upon you the necessity of avoiding all attempts at fogging your picture as a means of obtaining negative effect. This is a great error, and one into which you will be liable to fall, from the circumstance that some authors speak of a degree of fogginess as an essential part of a negative.

Now, knowing what the true characteristics of a correct negative are, let us see how we can accomplish the task imposed upon us. The opacity on the sensitized collodion film depends primarily upon the time exposure, and secondarily on the development. But deep opacity of the high lights and transparency of the shades depend upon the intelligent application of both light and the reagents used in development.

An increase of light, either in duration or intensity, will produce more general action on the silver film, and consequently increase the tendency to fogginess; from this circumstance we learn to add more acid in proportion to the sulphate of iron in the developer. If the light be too intense or continued too long, the tendency to fogginess will be unmanageable. The light required must be just sufficient to yield by development a negative possessing clearly and distinctly the three gradations of light, middle tone, and shade above mentioned. As soon as we have managed to arrive at such a result, although the opacity may be far from being deep enough, the rest of the operation is easy enough.

Fix your model to your desire, and, instead of giving six or eight seconds as you did for the melainotype, try ten or twelve to begin with. Now let us proceed to the dark-room. Naturally, the actinic impression being more intense, the developing process will start with more rapidity; and consequently those parts first covered with the developer will be sooner finished, whilst the other parts are not yet finished. Besides this inconvenience it invariably happens, if you pour on your developer as you would collodion, that the force of the falling fluid makes a mark on the film which spoils the picture. Hence arises the necessity of floating your negative plate quite otherwise. For this purpose I recommend you to use always a porcelain or photographic ware dish of about 6 by 8 inches.

Lay your small negative in the front left corner of this dish with the collodion surface upwards; now, holding the dish in the left hand, incline the right side of the dish downwards, and pour into it so inclined a few ounces of the developer, and then quickly raise the dish so as to flow all the liquid at once over the surface. By this means you will avoid all the inconveniences of lines of breakage and other marks referred to. As soon as the plate is thus covered you can place the dish on the shelf or table before you, and can then take out the negative and watch the development. This process may proceed slowly or quickly according to circumstances. If it is tardy in beginning, the time of exposure was too short; if, on the contrary, the action is very rapid, the time was too long, that is with the developer recommended. Supposing the action to be moderate, but quick enough to be properly watched, you may conclude the

time to be about right. Allow the reduction on the film to proceed, increasing in intensity as long as no fogginess supervenes, or until finally the surface by reflected light appears to undergo a retrograde action as mentioned in the lesson on the melainotype. It is high time in this case to stop all further action by quickly and thoroughly washing the plate, and by then fixing in a bath of hyposulphite of soda, and again thoroughly washing.

If, on examination by reflected light, the picture appears still as an ambrotype, and by transmitted light the high lights are tolerably opaque, of course more so than the ambrotype, whilst the deep shades are still transparent, you have a picture from which we can now fabricate a negative in which the opaque parts shall be as dense as you may desire. At present it is not a negative—it is merely the foundation of a negative in which the grades of light and shade are present without the necessary degree of denseness in the opaque parts.

Intensifying of the Negative.—The plate so far prepared may be intensified either whilst it is still wet or at any time after it is dry. In the latter case, however, it becomes necessary to coat the four edges of the collodion film to the depth of one-sixth of an inch with negative varnish. This can be accomplished by dipping the uncut quill-part of a large feather in the varnish and then rubbing this part along the edge slowly—by capillary attraction a sufficient quantity of varnish will flow along the edge, and particularly so if you take care to rub the edge of the plate along that part of the quill where the varnish accumulates by its pendent position. As soon as the varnish has thoroughly indurated, that is, after the lapse of a few hours, the paper is immersed in water and retained there for a quarter of an hour, when it will be in the condition of the wet plate.

Intensifying Preparations.

No. 1.	Water	2 ounces
	Iodide of potassium	to saturation,	and afterwards			
	As much iodine	as it will dissolve.				
No. 2.	Pyrogalllic acid	12 grains
	Acetic acid	1 ounce

Take one drachm of No. 1, and dilute it with seven drachms of water, then flow the plate with this mixture, taking care to keep the fluid moving, by pouring it off and on all the while. By degrees the collodion film assumes a yellowish tone; at this stage you can wash the plate thoroughly and then proceed to the final operation.

Take one drachm of No. 2, and dilute it with seven drachms of water, to this add twelve drops of the nitrate bath and shake well, then keep pouring the mixture on and off the plate until the proper degree of opacity has been attained.

It sometimes happens that you have to proceed a second time with No. 2, before the opaque parts are sufficiently dark. I must repeat: be careful to shake the mixture well before you use it. Now wash thoroughly, dry, and finally varnish. Your negative is complete.

By this process of intensifying there is not much difficulty in converting an ambrotype into a negative; but such a negative will be defective from the fact that it possesses no intermediate tones; it is a mere contrast between intense blacks and pure transparent parts. On this account we are obliged to give more time, that is, more light, in order to produce a more general actinic effect over the whole surface of the plate, which, on development, yields a foundation-negative, that will receive by the intensifying solution any amount of deposition.

PREPARATION OF GUTTA-PERCHA PAPER.

BY ALEXANDER ARNSTEIN.

The gutta percha is cut in small pieces, and put in a wide-mouthed bottle, wherein benzole is poured sufficient to make a thick solution. The bottle is then put into a vessel containing water, and the whole placed on a stove, or near the

fire, stirring the solution from time to time. When dissolved, it is poured in the filter to draw off the liquid; what remains on the paper forms a paste that must be kept in a cool place. From this paste 6 to 10 grains are taken to the ounce of benzole (it depends on the moisture it contains). The bottle containing the solution is placed in warm water. A clear solution is obtained, which, if rightly made, looks like newly-iodized collodion.

Paper.—The paper is put in this solution, and left for a minute or two. Several sheets can be put in, being careful to avoid air bubbles; they are then hung up in a warm, airy place, and left so until the gutta percha is set, which takes a day or two; if not set, opaque spots will be seen when salted; although it does not affect the paper, it is better to avoid it.

Salting.—Ten grains of chloride of ammonium to the ounce of water. The paper takes the salt solution well, but I think a grain of isinglass to the ounce of silver is a great improvement to the tone of the picture.

The Silver Solution contains 60 grains to the ounce of water.

Washing.—As usual.

The Acetate Bath contains 1 ounce of acetate of soda to 6 ounces of water.

Toning Bath.—One grain of chloride of gold, 20 grains of borax to 8 or 10 ounces of water, prepared a few days before using, or any other toning bath, but must be weak in gold.

Fixing Bath.—One ounce of hyposulphite to 6 ounces of water.

Washing.—Two or three hours to be on the safe side.

The prints, when passed under the rolling press, look as if printed on slightly albumenized paper. Seeing the defects of photographic paper, I think that a waterproof solution will be applied to all kinds of paper. I hope that photographers will not be slow in giving to this process a fair trial. If any one should wish for a few pieces of prepared paper, and will send a directed stamped envelope, I will enclose a few pieces for cartes, as I cannot afford to send larger.

Ambleside, March 21, 1863.

THE STEREOGRAPH AND THE STEREOSCOPE.*

But if the single eye has this property, then the retina is not a surface—it must have a certain thickness of such a constitution as to be sensitive to the focal impression on any part of it; and if it has this sensitive structure throughout a certain thickness or depth, then the secret action of vision at long and short distances is solved. The problem, therefore, to be demonstrated seems to be, to ascertain, in the first place, what ought to be the thickness of a sensitive retina to comprehend pictures of objects between the extremes of the minimum distance of distinct vision and the maximum at an infinite distance, and then whether such a thickness exists. With an ordinary lens this is an easy task. The greater the power of the lens, the less will be the difference between the length of the principal focus and that of a very near object. The same law will prevail, with certain strictures and modifications, with the crystalline lens in the eye. But the method which I adopt, for ascertaining the capacity of the eyes for different focal distances, is altogether independent of the ordinary laws of optics, or at least it is developed upon totally different data from those previously applied to such discussions. The capacity referred to can be found in the following manner:—Take two words, for instance, *London*, printed in the same type, and paste them on a sheet of paper on the same line, so that the distance apart from *L* to *L* in either word shall be exactly the distance between the centres of the two eyes. Then on a line, parallel with the former, and distant from it one-quarter of

an inch, take two other words, as for instance: *Geneva*, printed in the same type (although this type may be quite different from that with which *London* was printed), and paste the word *Geneva* so that *G* is exactly beneath *L* of *London* on the left side, but let the distance between *G* and *G* in the two words *Geneva* be less than that between *L* and *L* in the two words *London*, as in the following example:—

London.	London.
Geneva.	Geneva.

Let the word *Geneva* to the right be loose (not pasted), so that it can be moved nearer or farther off. Now superimpose these words strabonically. It will be found that the word *Geneva* can be moved but a short distance to the left before it becomes impossible to superimpose *London* on *London*, and *Geneva* on *Geneva* at the same time. Be careful to obtain the exact point where the power of superimposition ceases. Then measure off, with a pair of compasses, the distance between *L* and *L*, as also between *G* and *G*, and ascertain the amount of their difference. Call this difference *Z* (equal to lateral difference). Next ascertain the distance of the eyes from the paper, when they see distinctly. Then say: As the distance between the centres of the eyes is to the distance between the eyes and the paper, so is one-fourth of *Z* to *X* (the longitudinal distance). A second proportion, as follows, will give the thickness of the retina. That is: As half the distance of distinct vision is to *X*, so is the distance between the retina and the crystalline lens to the thickness of the sensitive retina.

If the difference, *Z*, be greater than one-fifth of an inch, my own eyes cease to superimpose the objects with tolerable clearness. Assuming this quantity, then, as the limiting difference, and twenty inches the distance of distinct vision for my eyes, and, moreover, half an inch the distance of the crystalline lens from the retina, we have the following proportions:—

Inches.	Inch.	Inch.	Inch.
As 2·5 :	20 :	0·5 ($\frac{1}{2}Z$) :	·4 (<i>X</i>)

Inches.	Inch.	Inch.	Inch.
2ndly, As 10 :	·4 :	·5 :	·02 (thickness of the retina).

From this calculation I infer that, if the retinae of my eyes are sensitive not alone on their surface, but to the depth of two one-hundredths of an inch = one-fiftieth of an inch, then these retinae are in a condition to bring all objects to a focus whose distances vary from 20 inches to an indefinite quantity, and consequently to see all objects between these extremes. If an object be nearer than 20 inches, the conjugate focus will be longer, or beyond the retina; still such an object will be seen (although indistinctly, because the rays pass through the retina, just like an object viewed on the ground glass when out of focus and too near to it).—The calculations of Olbers, derived from quite a different source, that is, by taking into consideration the radii of curvature of the crystalline lens, its refractive power, its distance from the retina, and the refractive powers of the other media engaged in producing vision, resulted in obtaining ·143 of an inch as the difference between the conjugate focal distance of an object four inches remote from the eye, and of an object at an infinite distance.

Eyes that are endowed with the power of seeing distinctly at the distance of four inches, as also at an indefinite distance of a mile or more, would certainly be able to superimpose objects placed at a greater disparity apart than I can; and if there are such eyes so remarkably endowed, then the quantity which Olbers obtained would coincide in some measure with the quantity obtained by my method, which can be more relied upon, because it is founded on the capacity of the eye as derived from absolute experiment, and not on the assumption—that if the eye were in every respect like an ordinary refracting mirror, then optically

* Continued from p. 615, vol. vi.

from given data we should obtain a given result. I must confess, however, that I have not seen any eyes possessing the capacity in question from which the deductions were obtained. Eyes that see objects distinctly at the distance of four inches are abnormal, and are incapable of seeing objects distinctly at very great distances; so that the capacity, that is, the difference between the minimum and maximum focal distance in most eyes, is, probably, nearly the same quantity, and that at the very utmost it probably never exceeds the one-fiftieth part of an inch. I think it will not exceed this quantity from another fact, namely, that, having exercised my eyes exceedingly in experimenting with the superimposition of objects at variable distances, the faculty of discriminating the amount of this capacity or quantity has become very sensitive.

If, then, the retinal layer has the thickness of one-fiftieth part of an inch, and if the structure of the retina is sensitive from the anterior to the posterior part, that is, from the hyaloid membrane on one side to its contiguity with the choroid membrane on the other, then the eyes are endowed with the power of distinct vision at variable distances *without changing* the shape of the crystalline lens, or its position in the eyeball. In the first place there is no authority, derived from the anatomy of the eye, to conclude that the crystalline lens assumes a different shape when viewing near or distant objects. Secondly, there is no authority, derived from the science of optics, permitting the conclusion that the different layers of the crystalline lens act independently of each other, or in partial combinations involuntarily for different distances. To admit such a phenomenon would be equivalent to admitting that the separate lenses of an achromatic combination had each its separate focus, at which a separate image would be produced. Thirdly, there is but little authority that will warrant us to conclude that the crystalline lens has a motion in the eyeball, produced by the ciliary muscle or the erectile tissue of the ciliary processes.

Such motion cannot be demonstrated to exist; the conclusion alone has been drawn, that if such a motion did exist, it might perhaps be produced by such means, but certainly not by the action of the muscles of the eyeball. It seems to me, therefore, a reasonable conclusion to reject all hypotheses which have so little ground for adoption, and to admit one which possesses all that is desired to satisfy the requirements.

It has been proved, by microscopic observations, that the retina is not a surface, that the retinal expansion is quite appreciable in depth, consisting of several layers of nervous fibres, vesicles, granules, and rods, quite transparent and in continuity with each other: so that it becomes a conclusion warranted by the data, that the conjugate foci of objects at different distances in front of the eye are to be found at relatively different distances among the radiating bacillar projections, and nervous fibres that make up the substance of the retina, and that the impressions thus made at different distances on either eye will, by the crossing of the nerve fibres at the optic commissure, or elsewhere, or otherwise, produce the solid picture of the reality in the sensorium.

The calculations of Olbers furthermore presuppose that the eye changes its form some way or other in order to view the extremes of minimum and maximum distance; but I maintain that, as indicated by the experiments of superimposition, the eyes can view minimum and maximum distances of great diversity at the same moment of time; for instance, the moon and a church-steeple can both be seen at the same time if situated in a proper angular condition for the purpose. Now, if this be so, if it can be proved to be so, it is evident that the eye, in the case supposed, *does not change* its form; and if it does not change its form, then the retina must consist of a transparent thickness for the reception of the conjugate foci of external objects; and the admission of both these properties of transparency and thickness of medium is simply the admission of two well-known facts; and, these facts being admitted, the rationale of vision at differ-

ent distances, and of solid pictures on the retina conjugate to objects in nature, or to their representation on the stereograph, is manifest and intelligible.

A person with one eye can never see perfectly the solid character of objects as comprehended by the operation of two eyes; for the superimposition of the two sides of an object cannot be performed by one eye. Nevertheless, a single eye can take cognizance of distance, which it could not do if the retina were simply a surface. If this be so, then the visual impression of lateral and longitudinal distances will give at the same time a conception of solidity, deduced probably from, or corroborated by, the sense of touch and by experience.—*Humphrey's Journal.*

THE NITRATE OF SILVER BATH.*

The nitrate of silver bath, undoubtedly, is the photographer's greatest difficulty. Being unfortunately required in large quantities, and of an expensive material (its preservation in a good working condition is one of the grand desiderata of our art), too much care cannot be bestowed upon its preparation. Perfectly pure ingredients are indispensable; and carefully re-crystallized nitrate of silver, obtained from a reliable source, should alone be employed. Some samples of the commercial nitrate of silver are found to answer fairly, but, as a rule, it cannot be depended upon. A good and easy test of the purity of this article, is the suspension of a piece of litmus paper in the bottle containing the crystals. If, at the expiration of an hour, the paper remains unchanged, the absence of free nitric acid is indicated, and, along with that, it may be presumed, of the other impurities of the adhering mother liquor. Good re-crystallized will always stand this test, but it is very rare for the commercial to do so. Fused nitrate of silver the writer has always maintained to be a great mistake, because of the probability of its being made from the mother liquor, from which a crop or two of crystals have been taken—the manufacturer thus being enabled to use up advantageously all his solution—and, therefore, instead of its being the purest kind, it is generally the very reverse, with the additional danger of its being further injured by the presence of nitrate of silver from carelessly over-heating during fusion. This fact is now so fully recognised, that the employment of this form of the salt has almost ceased. The objections, of course, do not apply to the carefully fused sample, prepared under the watchful eye of the well-skilled manipulator, but even then it possesses no advantage over the re-crystallized.

So much difference of opinion prevails with regard to the bath being *neutral* or otherwise, that a set of very careful experiments were instituted to ascertain what were the real facts of the case; and, in order to guard against error, the experiments were repeated three times, the first and second being a year apart. I would strongly advise photographers to make trial of the matter for themselves, for they would find in the knowledge and confidence thereby obtained an ample compensation for the little trouble occasioned. There is, however, much uncertainty in these photographic experiments, unless great precaution be used to guard against error—the danger of misreading or misinterpreting the results of our experiments, arising from the complexity of the subject with which we are dealing, and our proneness to overlook or disregard some seemingly trifling condition—a trifle which may turn out to be of the utmost importance. If photographers were more careful experimenters, there would not be such contradictory statements put forth, nor would such a mass of crude hypotheses pass unchallenged as are now met with among us.

Passing on to the experiment, I will detail, as clearly as I can, the method employed, and the results obtained in my hands. In the first place, it must be clearly understood

* From Ponting's "Photographic Difficulties." We have generally condemned the use of acetate of silver in the bath; but, for the purpose of giving impartially both sides of a question, upon which we have recently had many questions, we reproduce this interesting chapter.

that the collodion used in this and all other experiments, was my own make, and at its ripe and colourless stage. With other collodions, it is possible the results may be different.

A neutral bath being necessary to start from, it was obtained by dissolving two ounces (avoirdupois weight) of re-crystallized nitrate of silver, in thirty ounces of distilled water, very carefully distilled at a low temperature over a gas flame. The solution was then divided into two equal portions, of fifteen ounces each, and placed in perfectly clean and new bottles, to one of which was added a small portion of oxide of silver, made by dissolving a few grains of the same nitrate of silver in distilled water, and precipitating the oxide with liquor potassæ, P.L. (solution of caustic potash of pharmacopœia strength) ascertaining, first, that the liquor potassæ was perfectly caustic, by finding that it would not effervesce on the addition of a dilute acid. The oxide of silver was then thrown on a filter, and washed with distilled water. In the first experiment, in March, 1859, I mixed together five ounces of each of the two solutions of nitrate of silver, used the resulting bath, and obtained a clean and satisfactory picture. I then added one ounce more of the solution with the oxide, and on again taking a picture, found it foggy from the alkalinity of the bath, its neutral condition being restored by adding another ounce of the simple solution of nitrate of silver. On repeating the experiment, however, in March, 1860, a different result was obtained. The two solutions of nitrate of silver were made as before; but it being, at the time of preparation, very dull weather, quite unsuited to experiments of this kind, the oxide of silver remained on the filter several days, having three or four portions of distilled water poured over it each day; and in this way, I believe, all alkalinity, from the presence of liquor potassæ in the precipitate, was entirely got rid of. The solution of nitrate of silver saturated with this oxide, while still moist, and allowed to stand over it several days, with frequent shaking, gave a clean picture free from fogging, when it was used without any admixture of the other solution. Thinking, from the discrepancy between this and the former experiment, and from the recorded experience of others, that some fallacy lurked in the experiment, a further additional trial was made, and a precisely similar result obtained. It would thus seem that the alkalinity, deemed to arise from the oxide of silver, is really due to the presence of a minute portion of the potash solution adhering to the oxide.

Having in this way obtained a perfectly neutral bath, which had neither acid nor alkaline reaction on test paper, further experiments were made to ascertain the effect of the addition of *acetate of soda* and *acetic acid* to the bath. For this purpose a pair of landscape lenses, fitted to a binocular stereoscopic camera, were used, the lenses being $1\frac{1}{2}$ inch diameter, five inches in focal length, and stopped down to three-eighths of an inch. This is a very convenient camera for such experiments, as it enables one easily to try the result of two different times of exposure under the same circumstances. The object was a lot of dingy old chimney stacks, roofs of houses, and a distant church tower, visible from the operating room, giving near and distant objects, and brightly illuminated by a March sun; care being taken to select a day when the light was uniform, otherwise these comparative experiments would be of little value. A plate that had been immersed in the above neutral bath was exposed on one half of its surface three seconds, and on the other half six seconds, developed with the usual one grain to the ounce pyrogallic developer, with acetic acid. Ten drops of solution of acetate of soda* were added to the bath (of about ten ounces), and a pair of negatives taken, giving precisely similar exposures to those of the first pair. Five drops of glacial acetic acid were now added to the same bath, and a third pair of negatives taken, keeping, of course,

to the same exposure, each pair thus consisting of a negative taken in three seconds, and one taken in six seconds. The three negatives were printed together, on one piece of paper, the first negative having to be screened about one-fourth of the time, to prevent its being over-printed. A descriptive account of the negatives is annexed, in a tabular form, for easy reference.

A. NEGATIVE No. 1. B.

THREE SECONDS' EXPOSURE.

A weak purplish sky; all the details of the illuminated parts of the picture are given, with some of the brighter portions of the shadows; no details in the deep shadows; prints dark and heavy.

Exposure too short.

SIX SECONDS' EXPOSURE.

This is a good negative of a purple red colour, full of half tone, and details of the dark parts well out; a little wanting in force, but furnishing a good print.

Exposure about right.

C. NEGATIVE No. 2. D.

THREE SECONDS' EXPOSURE.

In this the effect of the acetate of soda is very apparent; sky intense; a much better negative than the one above; no details in the deep shadows; prints dark, but brighter than the one above.

Exposure too short.

SIX SECONDS' EXPOSURE.

A very intense negative; a black sky, which could not be printed through; details of the dark parts well out, but being somewhat over developed, it prints with too strong a contrast between the lights and shadows.

Exposure about right.

E. NEGATIVE No. 3. F.

THREE SECONDS' EXPOSURE.

This is a good and vigorous negative; sky orange red; the details are all well out in the dark parts; half tones good; gives a good and forcible print, and with another second's exposure, would have been, beyond question, the best of the lot; as it is, it is doubtful whether this or the B of No. 1 is the better.

A little under exposed.

SIX SECONDS' EXPOSURE.

This is a very intense negative, with orange sky, and the other portions of the picture of a red tinge; takes a long time to print; the sky weak from exposure, and prints through, but the other parts vigorous and full of detail and half tone.

Over exposed.

To sum up the results of these trials, it is clear that the addition of acetate of soda and acetic acid does not make the bath work slower. In fact, if these experiments may be relied upon, it is shown that the action of the bath is thereby accelerated, for the pair of negatives No. 3, are very much better than No. 1 pair, and there would be considerable difference of opinion among photographers as to whether the negatives B or E were the better, though the latter was exposed only half the time of the former. Although I had, for years, employed and recommended to others this method of making the bath, I was not at all prepared for this result. For myself, I had long been abundantly satisfied, as the result both of my own experience and that of others, that this preparation furnishes the operator with an organic matter, not injurious to the bath, which gives him a controlling power over it, so as to enable him to increase or diminish the intensity of his negatives; and, in addition to this, there is plentiful proof that the bath is, by its use, preserved in good working order for a longer time than by any other method.

This accelerating action of acetate of soda with acetic acid (for they should always be used together, as these experiments demonstrate), being quite unexpected, some experimental negatives taken a year ago, were examined, to see

* Acetate of soda, 130 grains dissolved in one ounce of distilled water, to which is added sufficient glacial acetic acid to make it redden litmus paper, say ten drops.

if they would bear out this statement; and, on submitting them to careful inspection, there could be no doubt of the fact. The trials were made at the time to demonstrate the increase of intensity obtained, without adding to the exposure; and, as they proved that no further search was made, and as no prints were taken from them, the difference was not so manifest. In order still further to be satisfied that the result in question was not due to an accidental increase of light in the favoured negative, a further set of experiments was made, with a fresh sample of collodion about a month old (the previous one being about nine or ten months old), commencing with an entirely new neutral bath, and, altering the order of the previous experiment, acetic acid alone was added for the second trial, the third attempt being with both acetic acid and acetate of soda. The result was quite confirmatory of the first set of experiments. The time of exposure was increased to four and eight seconds respectively. The four seconds exposure was abundantly long enough for the first and third plate; the one with acetic acid alone was much slower than the other two; but the third negative, with acetic acid and acetate of soda, was again, unmistakably the best of the lot. Of the negatives with eight seconds exposure, the first, with neutral bath, is so much over-exposed as to be useless; the second, with acetic acid alone, is about right; the third, with acetate of soda and acetic acid, is considerably overdone, but gives a tolerably good print notwithstanding. The slight difference between this negative and the corresponding one of the former experiment, is probably due to the fresh sample of collodion, but is confirmatory of previous experience, which showed that the operator might, with this bath, much increase his exposure, to get out any very dark portions of the pictures, with greater impunity than when using a neutral, or nearly neutral, bath.

PHOTOGRAPHS IN PRINTING INK.

[Mr. John Pouncy, of Dorchester, has addressed to the Editor of the *Times* the following letter, in answer to one from Mr. J. W. Osborne, as it was not inserted in that journal he asks us to publish it. As we gave an abstract of the correspondence in the *Times*, we, in fairness, insert Mr. Osborne's reply. We must add, however, that we are not aware of the existence of any evidence which proves that Mr. Pouncy applied the principle of the *transfer*—the question really at issue—before Mr. Asser, Mr. Osborne, or Col. James. Mr. Pouncy's first published carbon process had no relation to the use of printer's ink.—Ed.]

I claim your indulgence for a few lines in reply to the letter of Mr. J. W. Osborne, which appeared in the *Times* of the 17th inst., with regard to my newly-patented process for producing photographs in printer's ink. Notwithstanding all that is therein stated with such "official authority," I, as an honest Englishman, not only claim the "earliest conception of the idea," but also the practical working out of the same to the production of a picture, direct from a "negative," hitherto unequalled in any system of printing photographs in carbon. This I demonstrated before a meeting of the London Photographic Society at King's College, on the 4th of November last; and although Mr. Osborne seems to think so little of the specimens then exhibited, how is it that, with all the resources at their command, neither he nor Colonel James has responded to the challenge I then gave to produce anything of the kind in this department of carbon printing? My original carbon process was first brought out in 1858, and publicly discussed before the Photographic Society of London in January, 1859—a fact which Mr. Osborne altogether ignores, and this included a process on stone, from which copies could be printed in printer's ink. After this followed M. Asser and others; but I have failed hitherto to see that they have attained to anything more in this direction than photolithography, and that only in copying prints and maps. The printing of Domesday Book from stone or zinc is based on the principle of my original carbon process, as acknowledged in the preface to Sir Henry James's book. There is, however, a vast distinction between copying line engravings, maps, &c., and photographing pictures from nature or life; the former requiring nothing but black and white, while the other must be composed of the minutest gradations of tone. Here lies the

value of my "special method," as Mr. Osborne is pleased to style it; and that my "half tones" are equal to photographs produced by the nitrate of silver process from the same negatives, I can assert, without fear of contradiction, before any competent and unbiassed tribunal. Those who have any misgivings as to the results at which I have arrived will have ample opportunity of satisfying themselves, by an inspection of the specimens which will be shown at the approaching exhibition of the Photographic Society of Scotland.—Your obedient servant,

JOHN POUNCY.

Dorchester, February, 18, 1863.

Proceedings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

THE Annual Meeting of this Society was held in Myddelton Hall on the evening of Wednesday, March 18th, Mr. G. DAWSON in the chair.

The minutes of a former meeting having been read and confirmed, Miss Barfoot and the following gentlemen were elected members of the Society:—Messrs. G. Hooper, W. Braine, J. Davis Burton, Wm. Henry Mertens, Jas. Mitchell, and Ed. George.

MR. G. WHARTON SIMPSON exhibited a specimen of enamelled paper for photographs, which he had received from Herr Liesegang of Elbertfeld, who stated that it was regarded with much favour in Germany. Mr. Simpson also exhibited some card portraits printed thereon, which were very brilliant and rich in tone.

THE CHAIRMAN called especial attention to the depth and richness of the prints, which were generally admired.

THE SECRETARY then read the annual report, which congratulated the members on the satisfactory position of the Society. The financial statement showed that at the last annual meeting there was a balance in hand of £15 6s. 9d.; and that after paying all expenses, the balance now presented was £21 18s. 7d.

The report having been read and adopted, the meeting proceeded to the election of officers. Whilst the routine proceedings necessarily were in hand,

MR. SIMPSON, at the request of the Chairman, entered into a few further explanations regarding the enamelled paper, which seemed to excite much interest. He stated that on examination he found that a surface of albumen rested on a surface of enamel, and that the image was confined to the albumen surface. A piece of the paper where an air bubble had occurred in sensitising, illustrated this, for the albumen had been removed during fixing and washing, but an enamelled surface was still found. He had treated the paper the same as albumenized paper, floating on a 60-grain bath, toning in a bath of gold and acetate of soda, and fixing and washing as usual. With each of the pictures he had printed he had also brought a print on ordinary albumenized paper from the same negatives. The superiority in depth and richness of tone in enamelled prints was very striking, whilst the fine surface unquestionably rendered more detail. So far as it was at present possible to judge, the paper would be very valuable for card portraits. He ought to add that it was quite exempt from meanness.

Some conversation on the subject followed, especial attention being directed to the freedom from meanness, and a general opinion in favour of the paper was expressed.

MR. MORLEY showed some very fine negatives with prints therefrom. They were produced by plates well washed after sensitizing, then coated with dilute albumen, dried, and subsequently coated with a solution of gallic and tannic acid.

MR. MOENS having relieved the Chairman of his duties, MR. DAWSON read a brief paper on the lenses used for instantaneous photography, in which he expressed a strong preference for the use of single lenses with small aperture as giving so much better definition to the distance as well as the foreground, instancing many of Mr. Wilson's slides as illustrating the value of this mode of working,* and exhibiting many of the slides in

* It is a mistake to imagine that Mr. Wilson uses a small aperture in instantaneous photography. Every photographer will, of course, use an aperture as small as the condition of the light, the nature of the subject, and the sensitiveness of his chemicals will permit; but the average aperture used by Mr. Wilson with a lens of five or six inches focus, is about half an inch or five-eighths, and he has recently been using a new form of single lens constructed for him by Mr. Dallmeyer, with the express purpose of giving good definition with a wide aperture.—Ed.

question. These were marked at the back with the name of the lens with which they were produced; a few of the earlier slides were produced by French single lenses, a couple by Jamin's quarter-plate portrait lens, several by Ross's $\frac{1}{4}$ inch focus single stereo-lens, and the remainder by Dallmeyer's new form of single lens; the size of the stop used, however, was not stated.

Mr. Dawson also showed one of Harrison's new globe lens which he had been trying. The equivalent focus was about $10\frac{1}{2}$ or 11 inches; he had tried one or two negatives, but the day was very unfavourable for such a test. An image consisting of a test object of a series of vertical and horizontal lines, was given quite free from distortion and well defined on a 12 by 10 plate; an hour's exposure being necessary in the very dull light of that morning. An image of the same object on the same sized plate was equally free from distortion, and as well defined with one of Ross's new triples of 9 inches focus. A pair of views, chiefly of house tops, taken with the two lenses in question, were also exhibited, in these the advantage appeared to be possessed by the lens of larger focus. They were produced with similar stops in about the same time, and both on 12 by 10 plates.

Mr. Dawson in answer to Mr. Simpson, said his test sheet was about 23 inches long.

Mr. Simpson remarked that in producing an image so large in proportion—about half the size of the original—the focus became of course practically lengthened. In answer to a question Mr. Simpson stated, that the price of the lens now exhibited was, he believed, £15. Mr. Martin said he had understood it to be £19.

After some further conversation, the names of the officers elected for the ensuing year were announced as follows:

President.—Charles Woodward, F.R.S.

Vice Presidents.—G. Shadbolt and G. Dawson.

Treasurer.—D. W. Hill.

Committee.—G. Wharton Simpson, W. Hislop, J. Shave, W. W. King, W. J. C. Moens, F. Bedford, T. A. Barber, E. W. Foxlee.

The proceedings then terminated.

PHOTOGRAPHIC SOCIETY OF PHILADELPHIA.*

THIRD stated meeting, held Wednesday, February 4th, 1863. Meeting called to order by President C. GUILLOU.

The room committee reported having completed the furnishing of the room, and urged the members to donate to the library such books and back numbers of the journals as they could spare, and to make use of the walls of the room to display photographs of interest, which they could change from time to time and thus by variety keep up the attraction. They report that to Mr. Hugh Davids they are indebted for the gift of a book-case; and to Mr. Pearce for a bulletin board.

Corresponding Secretary COLEMAN SELLERS read a letter from Mr. Robert Shriver, Cumberland, Md., thanking the Society for the compliment paid him in electing him corresponding member. Also a letter from Mr. Charles Waldack, Ghent, Belgium, full of kind wishes. One from Mr. Black, of Boston, promising some large photographic views, and giving a short history of the spirit photographs. One from Messrs. Seely and Bartlett, of New York, offering to donate to the Society the back volumes of the *American Journal of Photography*.

Messrs. Robert Wise, and Robert Sturges, were elected members.

The SECRETARY, Mr. J. C. BROWN, then read a letter which had been published by Dr. Childs, giving his account of the spirit photographs, and having his first proof of their genuineness in the fact that the New York Photographic Society pronounced them a humbug, as in the case of Galileo and others of the old philosophers in the days of darkness, and the discussion of the learned bodies of those days. During the reading of the paper quite a number of the spirit pictures were passed around for inspection, and were examined with interest, but did not strike any of the members present as convincing proofs of their being genuine. Various ways of producing the pictures were proposed, but as there were no believers in spiritation present, the argument was rather one sided, and the matter was soon dropped.

The PRESIDENT exhibited a number of etchings by Spackman, as an introduction to some prints made by a company in

New York, and which are to be printed from copper type said to have been made by a new process. He said he would not give any further detail of the process used further than that a glass was coated with some compound (as on the plan of Pretsch, which was, he believed, gelatine and bichromate of potash), and then dried. This exposed to the light under an engraving or an etching on collodion films, and then soaked in a liquid which would swell up all but the lines; on this surface the copper is printed direct, and this copper plate used as a block to print from. A sample of the copper plate was shown.

COLEMAN SELLERS read a paper on "Secret Formule," which was intended mainly to show that a pamphlet published in New York, and sold for three dollars, was descriptive of what had been long known, viz., that nitrate of ammonia added to the silver bath would allow a weaker solution of silver to be used for albumen paper, and the fuming with ammonia would surpass the requisite alkalinity without injury to the surface.

The PRESIDENT passed around for inspection some of the negatives made at the Imperial printing office of Vienna, and which consisted of films separated from the glass. He supposed that gelatine was the substance used, but the gentleman who had brought them to him was no photographer and could not describe the process, although he had seen it at Vienna.

The SECRETARY exhibited some prints from negatives made into a six-inch focus globe lens, and stated that he had heard that these new lenses were considered quick workers, but he did not think so. That he in company with Professor Fairman Rogers had taken a short photographic excursion, and that he had taken his six-inch Harrison globe and a Voigtlander orthoscopic lens of ten or eleven inch focus. He had exposed five or six plates, but that the day was so cold that the films were frozen (he was working wet collodion), and that with the Voigtlander he could get better definition with a large opening and could work quicker than with the Harrison. He merely wanted to say that he had been disappointed in the rapidity of the working, and did not think he could secure clear definition except with the very smallest stop.

Professor ROGERS was of opinion that the test of that day was hardly a fair one, as it was very cold, and his own dry plate seemed to take longer exposure than usual. He alluded to the freezing of the wet films, and said the crystals were very beautiful thus formed. He had never had much experience with the working of wet collodion in cold weather, but presumed Dr. Hayes's experience in the Arctic regions would throw some light on it.

Mr. J. P. SARGEANT said that Dr. Hayes had laboured under many disadvantages, not having any practical knowledge of photography, but that his negatives were quite good considering the circumstances, and had not heard him complain of any trouble except what were incidental to young beginners.

During this conversation, Mr. Hugh Davids, who is a landscape painter and has a room over that of the Society, retired for a few minutes, and returned bringing with him a negative and print from it, which he had made with an eight-inch Harrison globe, at six o'clock p.m., in the latter part of August last; the subject was principally foreground of weeds and stones, with dense masses of trees for the background; size of plate 8 by 10, exposure, wet, forty-five seconds; it was fully timed. He said he considered the globe lens as a quick worker, and had used a large opening in making the picture exhibited, which was very sharp in all parts of the field.

COLEMAN SELLERS said he had tried the identical lens in presence of Mr. Browne, and had produced a good picture on a cloudy day in less than one minute; he did not think them slow workers, but hoped some of the gentlemen present who had these lenses would give some account of their experience with them.

Mr. E. BORDA had been using the globe lens for a long time, and considered them very quick; with the smallest stop less than one-eighth of an inch diameter, he had produced a good picture wet, in a fraction of a second, and with tannin plates in fifteen seconds by fuming. This led to many questions as to the particulars of his fuming, which Mr. Borda answered substantially as follows:—

The plan of fuming plates had been suggested to him by Mr. H. T. Anthony, who had tried it some two years before he told it to him; but that Mr. Anthony fumed his plate before exposing. Mr. Borda fumed after exposing and before developing. He now fumed at least nineteen out of every twenty plates exposed; he could accomplish two important results: first, he could diminish the time of exposure; second, he could

* From the *American Journal of Photography*.

so modify the development as at all times to secure good detail in the foreground, while his clouds and distances were well preserved. He used ammonia diluted, and fumed for a longer or shorter period, according to the effect he wished to produce. When the exposure had been very short, he "gave it a pretty stiff dose;" but with long exposure he would not let it be but a few seconds in the gas from dilute ammonia; say one ounce of concentrated ammonia to two ounces of water. The development was conducted by wetting the plate, then using weak pyrogallie acid and a great deal of acetic acid; he had operated on a plate in this manner for one hour without staining or fogging it in the least. He could not, without an actual exhibition of his mode of operating, give a full account of time and quantities, as both were dependent on experience and practice, but he was very cautious in his manipulation, using his silver drop by drop, so as to feel his way with the development.

Mr. FASSITT had been present some few days ago when a twelve-inch Harrison globe lens were tried. He had seen three exposures made, as objects across a street, that with forty-five, forty, and thirty seconds' exposure the negatives were over-exposed; he should have judged seventeen seconds would have been ample time; he had never considered them slow workers.

Professor ROGERS was of opinion that in all experiments to determine time, the slide of the shield should be marked, and then when closed to begin with should be opened one inch at a time, giving from three to five seconds difference between the spring and the developed plate would show what time was best for the subject.

The PRESIDENT asked if any of the gentlemen present had tried formic acid as a developer? He had had given to him on that day a translation from one of the German journals (which one he did not know), describing a quick developer of 200 parts water, 14 parts pyrogallie acid, 26 parts formic acid, and twenty parts alcohol. He had tried it, but not enough to judge of its value.

Mr. DAVIDS had been using formic acid with the proto-sulphate of iron, and thought it an improvement.

COLEMAN SELLERS had used it for a great while, but did not think it was of very marked advantage; he was of opinion that in the formula given by the President the omission of any retarding acid would make the picture flash up quick, but would be apt to produce stains, formic acid not being a very powerful reagent, except when warm, as one of its properties was to reduce silver from its salts when hot.

The PRESIDENT had been promised by next meeting some copies of "greenbacks," producing the colours in the bank note, and that (as had been represented to him) in so perfect a manner as to defy detection.

The meeting then adjourned.

Correspondence.

PHOTOLITHOGRAPHY.

DEAR SIR,—I beg to enclose you a specimen of a transfer exactly as it was taken from the ink. The method by which it is obtained is at once simple and easy, securing the minutest detail, without the labour and risk of washing off the gelatine that has not been acted on.

After a print is taken from the printing frame, it is laid on its back on the surface of clear cold water, and allowed to remain till the gelatine can be traced on the surface. It is then removed and laid face down on a sheet of plate glass which has previously received a thin coating of greasy ink, and gently rubbed over the back, so as to bring the drawing into close contact with the ink. On removal, it will be found that the ink has attached itself to those parts only which have been acted on by light, the ground remaining perfectly pure and clean. If the quantity of ink is found not sufficient the process can be repeated till it is so. The coating of gelatine should be strong, and the paper, which I find gives the finest results, is albumenized, the surface of which has been rendered insoluble by straining.—I am, Sir, yours respectfully,

A. WOOD.

[The transfer received is clean, crisp, and sharp; and altogether, so far as our eye—not practised in lithography—can perceive, very good.—Ed.]

PHOTOGRAPHY IN NEW YORK.

MY DEAR SIR,—I owe many apologies to all my friends for shortcomings. My excuse is illness. Pertinacious attacks of pleurisy and bronchitis have confined me to the house for some months, and photography has been at a discount. My amusement has been printing a newspaper, of which I send two first numbers, and will send regularly. This sheet is "club" entirely, and we hope to print articles from the Club which will be worth reading.

In regard to the "Brass Toning," Coleman Sellers, Esq., writes me that he has introduced it into the photographic department of the Sellers Iron Works, of Philadelphia (where an immense deal of work is done in photographing models, drawings, castings, plans, &c., &c., connected with his business), with great success. This photographic department is of great advertising value to his Works, as he sends (in lieu of a long reply to inquirers about any machinery) one or two stereoscopic pictures of different sides of the machine, and the thing is seen and understood at once, and these pictures are seen and criticised by dozens, while a description would only be read by the person to whom addressed. The only talk here for a month past has been "Fumination," which has been harped upon, quarrelled over, and peddled out for three dollars. The experiences of Anthony's Fuming Process are curious. Spirit Photography is having a run also. This humbug is certainly well managed, and it is surprising that the Boston Yankees even can gull so many men of fair knowledge. The *Banner of Light* (Spiritualist paper) suggest that a Committee be appointed from photographers and from believers, one half of each, and they do go into a full investigation of the process. If this is done we can know something about it. One fact somewhat curious is the depreciation of prices of photographic work here, while all materials have appreciated. Gold and silver have almost doubled in value on account of the depreciation of our currency, while the finished pictures bring but half the price of two years ago. Cartes de visites are advertised at \$1.50 per dozen, at present rates of exchange about 3s. 8d. sterling, and yet the rush of business never was so great. To have a negative taken now requires the filing of your name and appointing an hour several days ahead, and then, necessarily, you must take the first result of the sitting. In another week a dozen pictures are sent to your house, and you pay for them whether they resemble you or Tom Jones. Great business country.

Our *rear* this side of the Atlantic has got to be a national institution, and as such will probably be kept running for some time to come. We do everything here on a big scale. We can get up the biggest ghost stories, the biggest accidents, the biggest factories, the biggest men, and we have shown how we can get up the biggest rebellion, and the biggest guns and armies in the world, and bye-and-bye we'll show how we can get up the biggest peace on record.—Yours respectfully,

F. F. THOMPSON.

New York, March 5th, 1863.

IS ALBUMEN RENDERED INSOLUBLE BY THE SALTS OF SILVER?

DEAR SIR,—I think the following few experiments (from many others) undertaken in connection with my manufacture of albumenized paper, go far to prove that NO₃ bears a most important part in rendering albumen insoluble, as expressed by me at the late discussion on the paper of G. Price, Esq., read at the South London Photographic Society, last meeting.

As an introduction to the experiments, I will put the question, why is it really necessary the albumen should be rendered insoluble in sensitizing? To enable it to resist the action of *after chemicals* it has to be subjected to.

1st. Precipitate AgO, NO₃ by NaO, A+6aq; wash the crystals, or add them without washing, to a portion of albumen, we have then a *salt of silver* in combination with albumen and its allied elements and natural salts. Treat

these mixed precipitates with our ordinary fixing solution (NaO, S₂O₂) and they will be entirely dissolved.

2nd. Add a few drops of paper bath solution (equal to quantity taken for precipitation in first experiment) to corresponding amount of albumen. Here we have the appearance of real coagulation; not a mere precipitate diffused in a viscous medium as in first experiment. Now treat these precipitates with NaO, S₂O₂ when the silver salts alone will be dissolved leaving insoluble films of albumen, with traces of silver.

3rd. Take another portion of albumen and precipitate with NO₂. Here the coagulation resembles that produced in Exp. 2nd; carefully neutralize with KO, and treat with NaO, S₂O₂ the precipitate remains undissolved in our usual fixing agent as in Exp. 2nd.

In conclusion I have only to add that it will easily be seen by photographers having a slight knowledge of chemical operations, why the best results are produced by a strong silver bath for albumenizing paper. I should feel much obliged if some of your correspondents will try the above experiments, and report thereon in PHOTOGRAPHIC NEWS; not being aware of similar ones ever having been published, which, of course, is the only test of priority.—I remain, dear Sir, yours obediently,

FREDERIC W. HART.

52, Canterbury Road, Islington, N.

Photographic Notes and Queries.

COLOURED GLASS FOR DARK ROOMS.

SIR,—Allow us to correct some erroneous impressions as to the non-actinic glass for dark rooms. It is frequently called "silver-flashed glass;" the glass is, however, stained, not flashed; the difference being that in flashed glass the colour is blown, or flashed on by gathering on the blow pipe, first, some ordinary metal, and then some of the colour required; whilst stained glass is produced by floating over a sheet of ordinary glass the required preparation, and burning it in the kiln.

In a recent number you recommend, in your answer to "Excelsior," the glass with a mottled or stippled effect. This, however, is not a test, as it occurs in glass which will admit the actinic rays, and is in fact a defect in laying or burning in the stain, and also in its non-actinic properties, as will be seen by testing a piece over sensitive paper, when the mottled effect will be found to be reproduced on the paper, proving that the actinic rays pass more readily in some parts than others.

We have found by experience that the property of excluding the actinic rays does not depend alone upon the colour being produced by silver, but that it is necessary to test the glass, a plan which we now always adopt before selling it for that purpose.—We remain, sir, your obedient servants,

CLAUDET AND HOUGHTON.

[We recommend the glass with a mottled appearance, not because the mottling possesses any advantage, but because it is one of the indications of the silver stain, which we have always found non-actinic, and the mottling is the only visible guide to the eye, indicating the proper quality; and although it may originate in a technical defect, it is always more or less present in the glass stained with silver. When the stain is thin and the mottling very distinctly marked actinic light will be admitted as we have frequently pointed out. We have also sometimes examined glass not stained by silver, pot-metal, which is quite non-actinic, but it is rarely met with. Silver colouring is generally the most trustworthy. The technical difference between staining and flashing is unimportant to the photographer.—Ed.]

REVOLVING GLASS ROOM.

DEAR SIR,—I beg to thank you for the advice received some time since, respecting the photographic house I was then about building. I have just finished it, and think it is everything that can be desired or wished for; the following are the dimensions of it:—

Length	26 feet 6 inches.
Width	10 "
Height to eaves	8 "
Side lights	8 " by 5 feet.
Top	10 " by 10 "

The house is erected on 4 wood pillars 8 feet high, with a cross and curb on the top, and fitted with iron rollers acting on the top of the curb, and, by a simply contrived lever, it may be easily turned round by the persons inside to face any quarter that may be most desirable, and to get the best light on the sitter. Should any of your readers think of building a photographic house, I think they would not regret the trifling extra outlay, of having it made to turn round.—I remain, sir, your obedient servant.

CHARLES SCARFE.

Alford, March 9th, 1863.

THE SACCHARO-SULPHATE OF IRON versus "THE DOUBLE SULPHATE OF IRON AND AMMONIA."

SIR,—As a new developing agent has been recently introduced by one of the leading photographic firms, and is, therefore, likely to be extensively tried. I beg to call attention to the suggestion of an amateur made some two or three years ago, I believe in these pages, of the use of another double salt of iron as a developer. This is the saccharo-sulphate of iron. Upon reading the communication referred to, I at once procured some of the salt, and found that its properties, and the results produced by it as a developing agent, fully bore out the description given. It has no tendency to peroxidize, and the crystals retain their beautiful greenish-blue colour, when kept in a corked bottle apparently indefinitely. In solution it yields extremely clean and dense negatives, and the positives obtained by it are of a very pleasing tone. I should not have troubled you with this note had I not considered the saccharo-sulphate were worthy of attention in these days of "iron development," and a salt which I feel persuaded has never received, at the hands of photographers, a fair trial.—I am, sir, yours, very faithfully,

CYMBRO.

SPOTS ON DRY PLATES.

DEAR SIR,—In the News of the 6th inst., page 112, I see an extract from the *American Journal*, in which the author records having met with round insensitive spots on tannin plates, which had been first coated with albumen. I have very frequently met with similar spots in collodio-albumen plates (I adopt the plan of coating the plate with gallic acid before drying); can they have anything to do with the albumen?

Having very little time to devote to photography, I have not been able to trace the origin of these spots, but have noticed that when the plate was wetted, they have whitened more readily than the rest of the film, from which fact, I fancy that they arise from some hygroscopic substance, which attracts moisture from the air. Out of a batch of eleven plates lately exposed, and prepared at two different times (some being six months old), only one presented them. I have not noticed that they are worse from the development being delayed after exposure, but I never remember to have met with them on freshly prepared plates. Should you think this worth inserting in your next issue, pray make what use of it you please.—I am, dear sir, yours faithfully,

J. A. C. BRANFILL.

10, Bridge Street, Westminster,
March 16th, 1863.

[Perhaps some of our readers can throw some light upon this trouble, which must have occurred more or less in the experience of all dry photographers.—Ed.]

Photographs Registered during the Past Week.

- MR. JOHN STUART, Glasgow,
Two Photographs of Mademoiselle Vaneri.
- " " " of Miss Kirk.
- MESRS. ROBERT HILLS AND JOHN HENRY SAUNDERS, Oxford and Elton,
Photograph of "The Oxford University Crew, 1863."
- " " " of Bishop Tozer.
- " " " of Canon Stanley.
- MESRS. LLOYD AND JEFFERSON, Southampton, Lancashire,
Photograph of Rev. W. Landels.
- MESRS. BECKETT AND WILLIS, Scarborough.
Three Photographs of Elihu Burritt.

* * Photographers wishing the Publisher to register for them must fill up one of the printed forms themselves. The form can be had of the Publisher by remitting two stamps. Two or more pictures can be entered on one form, but each must be separately described.

The fee for each picture is 1s. 3d.

Talk in the Studio.

PHOTOZINCOGRAPHY.—In the report of the Topographical Department, with reference to photozincography, Sir H. James states that photozincographs are now produced by him from nature, and any number of copies can be taken that may be required; the beauty, extreme simplicity, and cheapness of this process, he adds, are certain to cause it to be very generally adopted for producing illustrations to works on all kinds of subjects.

THE FIRST PHOTOGRAPHS OF THE PRINCESS OF WALES.—We have pleasure in stating that our valued friend and contributor Mr. F. R. Window, had the honour, a few days ago, to take the first portrait of Her Royal Highness the Princess Alexandra since her marriage. His Royal Highness the Prince of Wales, and their Royal Highnesses Prince and Princess Christian, the Princesses Dagmar and Thyra, and the Princes Frederiek and Vladimir also sat to Mr. Window, who secured some of the most pleasing portraits that have been issued of the Royal sitters.

RAPID TANNIN PLATES WITH A BROMIDE ONLY.—Major Russell, in a recent letter we have received, says:—I have lately found some important improvements in preparing dry plates. In investigating the method recommended by Mr. Keene, but using tannin alone, I find that a considerable increase of sensitiveness is obtained by washing off the tannin before drying, but that no difference is made by leaving nitrate of silver in the film before applying the tannin, except that a liability to stains is thus incurred. I also find that bromide alone in the collodion is twice as sensitive as 3 parts bromide to 1 part iodide, which mixture is more sensitive than any containing less bromide. The bromide requires different treatment throughout to that required by iodide; and the best way of working has not yet been determined in some points, but it seems to produce a better quality of negative for landscape views, and to work with greater certainty than iodide; the carbonate of ammonia developer works better than acid, silver, and pyro, with bromized collodion. By both the improvements which I have mentioned, not less than three times as great sensitiveness is gained, I think, besides the advantage given by the ammoniacal developer.

VIGNETTED BACKGROUNDS.—Mr. A. H. Wall informs us that he is now preparing a class of pictorial backgrounds, which he anticipates will be useful to many photographers. They consist of vignetted landscapes in which the formal ugliness of the oval, often given by the common vignetting glass, is avoided, and the time saved which is necessary to secure good results, by other methods. The sole care with these backgrounds will be to get the figure into the right position in relation to the landscape, and in printing to cut off the figure also in proper relation. A vignetted print with a suitable pictorial background, is often very pretty.

To Correspondents.

CORNISH CHROM.—The chief causes of the flatness in prints No. 1 and 2, are, in the first place, over-intensifying in the negative, and, next, under-printing. The coarseness and granular texture in No. 3 are partly due to a coarse film, a little over-intensifying, and partly to meanness in toning.

PERPLEXITY.—The difference in weight between a given measure of distilled water and the same measure of bath solution will of course represent the amount of nitrate of silver present, a slight allowance being necessary, however, for the water displaced, or increase of bulk produced by the nitrate of silver; but it is a somewhat roundabout method of getting at the strength of the solution. If you cannot afford a silver meter, and cannot satisfy yourself by means of precipitation by chloride of sodium, you may, by a little ingenuity, manufacture a meter with a test tube and a little mercury.

BICHLORINE.—There is much discrepancy of experience in regard to the darkening of negatives intensified with bichloride of mercury and iodide. We have some negatives so intensified, which have darkened after long printing, and some which are not changed by the same treatment. Some of our correspondents tell us that they invariably meet with this result, whilst others do not meet with it. We can only recommend you, if you find that such a result occurs in your hands, to adopt another method of intensifying. In some cases submitting the negative which has blackened to considerable heat restores its softness again. You can try if it answers with your negatives.

G. R. G.—We have never found the silver solution run in greasy streaks on the paper; but your suggestion of the presence of ether may explain it. The surface of the paper being in any degree greasy might also account for it, and with a horny, repellant surface, too short floating might account for it. To determine certainly the cause or remedy a few experiments with the materials used would be necessary.

PHOTO. Oxford.—The best apparatus for enlarging photographs to the size of life, of which we have any knowledge, is the solar camera, upon which many articles have appeared in our pages.

SUBSCRIBER T.—Citric acid will not decompose nitrate of silver if free nitric acid be present. The solution should be neutral or slightly alkaline. When you added citric acid and saw no change produced, and then found a white, curdy precipitate on adding a little ammonia, it was citrate of silver which was thrown down. 2. For toning it is better to work to a definite formula than to use the mixture you describe, the exact constitution of which it is impossible to determine. When the toning solution begins to turn reddish or purple it is an indication of decomposition, the colour being caused by finely divided metallic gold. 3. The whites of your prints "not being clear" arises from the fact that the negatives are thin, and that there is a little over-printing. 4. The stain on your vignette arises from the print having been touched with hypo before fixing; probably your fingers had come into contact with hypo and then touched the print in toning. 5. Your tones are good; but the portraits are over-printed. 6. The figure is lighted too much from the front; the negative is over-intensified; and the print is over-toned.

J. C. S.—Scratches can be polished out of lenses; but you will run a great risk of altering the figure and spoiling your lens if you attempt it yourself. 2. In good lenses each lens of the combination is burnished into its cell so that it cannot be placed in a wrong position. In cleaning others, if you are not familiar with their construction, the best plan is to replace each lens in its position before taking out the next; and it is not wise to often take your lens apart; as the interior surfaces of the lenses once properly cleaned ought not to need the operation very frequently, not being exposed. In the ordinary portrait combination the front meniscus lens has its convex side outwards; the back combination has the double convex lens outwards, and the concave lens with its concave surface towards the double convex lens.

SUBSCRIBER.—The toning process used by Mr. Lacy is to be used as we gave it, the only addition to the gold is the chloride of lime, which has a strongly alkaline reaction.

J. BUTLER.—In order to obtain a pyroxyline giving greater intensity, add a little water to the acids, or elevate the temperature, or both. The weaker the acids, and the higher the temperature up to a certain point, the more intense the collodion made with the cotton. The cotton will, also, be more soluble, and the larger the amount of cotton you can use, other things being equal, the more intense the collodion.

AN AMATEUR.—The operations you describe are of a very slipshod and unsatisfactory character; but we fear that in many commercial photographic establishments matters are managed somewhat loosely. We can only recommend you, however, to look upon such arrangements as "things to be avoided," no matter by whom they may be adopted.

A.—The addition of iron-developing solution to a silver bath will cause a reduction of a portion of the silver. If a small quantity only have been added, give the bath a dose of carbonate of soda and sun it, when in all probability it will, after filtering out the precipitate, work out all right.

J. F. TRELL.—The cards received have many very excellent qualities; the arrangement is artistic and pleasing, and the photography is brilliant and pure; the pictures altogether displaying good taste and careful manipulation.

MR. ENGLAND'S APPRENTICE.—We answer you under this name rather than your own, which you sign, out of consideration. We cannot enter further into a discussion of private or personal matters in our pages. Let us urge upon you, as an apprentice, diligence and a conciliating, or even submissive, demeanour to your employers, and you will meet with consideration in return. Depend upon it that it is a bad beginning in life for a youth to stand upon his real or fancied rights as to the amount of labour he will perform.

J. BURGESS.—We have not met with any such experience in using resinized paper. We will submit the specimens to Mr. Cooper and ask for his opinion. The examples of your early experience with it are very good indeed.

WILLIAM GREEN.—The spots in your print are similar to several which have been submitted to us recently. We can only conclude that it arises from some cause in the paper, since we know of no other cause. The effect is similar to that produced by the contact of acid with the print before the hypo has been washed out. The general photographic qualities of the print are good.

A DORSET AMATEUR.—The multitude of small black spots in the print doubtless arise from pin-holes in the negative, and these may arise from various causes; very probably in this instance from the supersaturation of the nitrate bath with iodo-nitrate of silver. See several articles on the subject which have appeared in our pages recently.

LECIA.—We cannot tell you exactly how to bromo-iodize your stock of plain collodion without knowing something of its constitution. Some samples are sent out requiring the addition of one ounce of iodizing solution to three of collodion; some one ounce to seven of collodion. Try, however, as follows: dissolve in one ounce of alcohol 24 grains of iodide of cadmium, 12 grains of iodide of ammonium, and 8 grains of bromide of cadmium, and add this solution to 7 ounces of the plain collodion. Should this prove too thick, then add a little more alcohol to reduce it to a working condition. 2. The opaque part of the roof overhead may be painted white or grey.

O. K. WALKER.—Your prints are not by any means the worst that reach us for examination; but there is still room for improvement. No. 1 is not quite sharp and a little over-intensified; No. 2 is better, but the light on the face is a little too evenly diffused, and the face lacks contrast a little; No. 3 the same characteristics, and a little over-intensified; No. 4 the same; No. 5 is soft and round, but lacks force a little. With continued care and perseverance you will soon attain excellence.

W. CALLOWAY.—Thank you for the address; it shall be forwarded to the right quarter. Regarding the paper to which you refer, we have not yet expressed any personal opinion of the practical result, but only of the principle. So far as we know it has not yet been produced quite to the satisfaction of the manufacturer.

OXALIC ACID.—We will take an early opportunity of examining the material received, and, if we can, help you in the matter.

Several Correspondents in our next.

AMATEUR PORTRAITURE.

THERE is no branch of the photographic art more fascinating than portraiture; and whilst excellence is generally supposed to belong only to the professional photographer, who is properly equipped with glass-house and proper accessories, there are few amateurs who have not made some attempts to depict the "human face divine," beginning by victimizing their friends as sitters, and ending by being victimized themselves in the demands for prints from some especially fortunate negative.

The much neglected glass positive was at one time most in favour amongst amateurs, but it now seems almost entirely discarded or forgotten, a circumstance much to be regretted, as some of these positives, when really good, were very beautiful. The fine white positive produced with the proto-nitrate developer, having a texture like matt silver, has rarely been surpassed by any class of photographs. The good alabastrine positive, either plain or skilfully tinted, possessed qualities we have not often seen equalled. But all these, as well as the common flat tawny positive, which was no credit to photography and could claim nothing of art, seem to have had their day, and may possibly, ere long, be named with daguerrotypes, as belonging to the extinct arts. Paper prints, especially card portraits, at present seem to claim almost sole attention from professional and amateur photographers.

Amongst amateurs a very general impression prevails that a glass house is necessary to portraiture. There can be no doubt that entire control over the lighting of the sitter is of great importance in securing the best results, and that to the professional portraitist it is imperative. There are, nevertheless, a number of effects possible to the amateur which are often pleasing and well worthy of a little attention. If other evidence or experience were wanting, the pictures contributed by Lady Hawarden to the recent Photographic Exhibition, furnished ample illustration of what might be done without the facilities of the professional portraitist. The majority of the pictures exhibited were taken in the drawing-room of her ladyship's residence; many of the figures being brought close up to the window, a portion of which, with the balcony, foliage, &c., beyond, were included in the picture. These, whilst satisfactory as pictures and artistic studies, independent of any likeness they might possess, were, we understand, not less valuable as portraits. The absence of the backgrounds and other accessories of the professional studio, we should regard in many instances as a positive advantage, as we have no wish to see amateurs competing with professional men in producing the conventional photographic portrait, however perfectly it might be achieved.

As a general rule the amateur is confined to the use of an ordinary room or the open air, and in both cases, by a little care and judgment, satisfactory lighting may frequently be obtained. To begin with the light in an ordinary sitting room with one window, with which we have seen very fine

effects produced, especially where the window was lofty. The sitter should, as a general rule, not be placed exactly opposite the window but a little behind it; a folding screen, or a clothes horse, covered with a white sheet, and placed parallel with the window may be made to throw a very good reflected light on the shadowed side of the face and figure. The nearer the sitter is placed to the window the more violent the contrasts of light and shadow will be; the further removed from the window the less violent the contrasts, but the longer the sitting necessary. On a bright day, and when the apartment is well lighted, the sitter may be placed at the side of the room opposite to the window. In some winter experiments we found that an exposure of thirty seconds was sufficient for a negative of a sitter placed twelve feet from a window, not much exceeding seven feet by four feet, using Dallmeyer's No. 1 B lens with open aperture. By a little management the actual furniture of a room may frequently be made to answer for the background. Care must be used, however, to avoid cutting up the picture by a number of spotty lights, and also to avoid having objects so much out of focus that their forms are not even indicated. A golden rule for portraiture in an ordinary apartment is to use a freely bromized collodion, which will not only give the maximum of sensitiveness, but will also check the tendency to undue contrasts which generally exists where the light reaches the sitter from one small source. As a further means of counteracting the tendency to black shadows, a full exposure should be given, and a strong iron developer used.

In open air portraiture as a rule an opposite tendency to that in an ordinary sitting room prevails. In the latter, as we have said, the tendency to undue contrast is common; in the former to want of contrast and consequent flatness. A collodion with a moderate amount of bromide is most useful here, and the presence of a little free iodine will be an advantage. Where it is convenient the sheltered angle of a wall or building should be sought so as to secure some shadow on one side of the face. With an equal light all around it is almost impossible to secure roundness or relief. If there be an open expanse of sky immediately behind the sitter it will be almost impossible to prevent fog from the mass of diffused light entering the lens. In all attempts at portraiture in the open air it is desirable to have the lens well protected from diffused light, the use of a cone of paste-board, blackened inside, which we have often recommended, will be found very useful. Where it is possible, a screen or awning should be placed above the head of the sitter to prevent the undue action of top light, of which there is, of course, a very large proportion. As regards background, a portion of a building, a portico, an arbour or rustic seat, a few shrubs or trees, or a combination of parts of several of these may often be made to give an excellent effect; and as in open air portraiture the exposure is often very short, a sufficiently small stop to give moderately good definition to the background objects, may without disadvantage be used. Where the amateur may prefer it a plain background may

easily be improvised: a blanket or a grey shawl hung across a suspended cord readily furnishes one. Or, where a vignette portrait is desired a less extensive background than this may be; for, as very little of the background will be seen in the vignetted picture, a large sheet of brown paper alone is sufficient to furnish a very excellent background.

An exceedingly good effect may sometimes be obtained by placing the sitter just within a doorway or an open French window, one half of the figure being in the full light, and the other in the shadow of the room. By a little care in arranging the position so as to avoid too much shadow, the effect here produced is very charming, the more so if a little foliage, &c., be seen beyond. In the case to which we are alluding, the camera is of course in the room, so that the shadowed side of the face is presented to the camera; and it is scarcely necessary to say that unless the shadow is kept very transparent and tender, a heavy inartistic effect must result. This, however, with sufficient exposure, and freely bromized collodion, may easily be secured: an exposure of about twenty seconds with the lens before referred to, giving an excellent result.

We have not here entered into the general question of portraiture, in reference to posing, expression, and general accessory, our sole object having been to throw out one or two suggestions in reference to methods of lighting not usually considered available for portraiture, for the benefit of amateurs not much experienced in this branch of photography.

MR. REJLANDER'S STUDIO.

MR. REJLANDER informs us that our misgivings as to the amount of light in his glass room have proved groundless in practice; it answers admirably. It has, moreover, rather less light than we stated. The door *a* in our diagram, which was not hung when we first saw the studio, and which we understood had to be glass, is simply of wood. We give some extracts from a letter in which Mr. Rejlander refers to some minor modifications which would be an advantage:—

"In juxtaposition to the cut of my studio you place an old cut (?) by Mr. Sutton, which looks very much like it, but I had never seen it before; if I had I should have adopted mine to his, not because of the length—which I find I shall have to do—but the slope, which is much better, and I should so far improve upon it as to slope *c,d*, as well, so as to get the glass more at an angle to the sitters.

"When I can afford it I shall make another alteration, instead of straight lines for the background and the side opposite the light, I shall have them both curved, perhaps a catenary curve.

"As to light, I have abundance without overflowing, but 'just the ticket.' As to ventilation, the undulated edges of the corrugated iron secure openings all around the house, beside the door and one opposite the sitter that you did not notice.—Yours truly, and always in a hurry when letter-writing,
O. G. REJLANDER.

P.S.—I took a group of twelve last Wednesday—plenty of light for all."

FUMING SENSITIVE PAPER WITH AMMONIA.

BY GEO. S. PENNY.

HAVING read the report of the discussion at the last meeting of the Photographic Society, following some remarks made by Mr. Debenham upon fuming sensitized albumenized paper, to say nothing of the remarks being illiberal, the conclusions are to my mind so illogical, that I cannot refrain from the attempt to prove the fallacy, not of Mr. Debenham's experiments, but of the argument he deduces from them.

It is a pity Mr. Debenham should have rejected the compliment offered to him for having proclaimed his failure, and claimed a success, because this can only be granted to him taking the word in the "Pickwickian sense." In the ordinary acceptation of the words, success and failure,

supposing the author of these remarks to have undertaken his experiments with the view of succeeding, surely he failed; if he entered upon them with the idea of failing, then he failed; or if he insists that success is the right word, why, he succeeded, but only in proving that *he failed*, not, as he asserted, in "clearing away a fallacy."

If every new discovery yielding contradictory results in different hands is to be shelved, or rather buried, in so unceremonious a way, it offers a serious bar to progress. Whatever the present value of this process, as it seems to involve a principle at present not understood, which may some day tend to important results, our aim ought to be to discover the *rationale* of its action, not to attempt to disprove facts.

Thinking that the question, as Mr. Malone remarked, might be one of manipulation, I have conducted a few more experiments with a view of determining how far that is the case, and also of verifying my original experiments, the result of which I sent you on a former occasion.

I now enclose some prints illustrating two series of experiments. For the first series I sensitized a piece of Collins' albumenized Saxe positive paper, on a 60-grain nitrate bath, acidified with nitric acid. The particulars are seen in the table below.

No. 1.—Not fumed.	Exposed 28 minutes.
2.—Fumed 3 minutes.	" 21 "
3. " 7 "	" 15 "
4. " 10 "	" 20 "
5. " 15 "	" 20 "

For the following series a piece of the same paper was sensitized upon the same bath reduced to 30 grains to the ounce.

A 1.—Not fumed.	Exposed 49 minutes.
A 2. " "	" 63 "
B 1.—Fumed 4 minutes.	" 49 "
B 2. " 15 "	" 23 "
B 3. " 30 "	" 24 "

The first series were exposed consecutively in full sunshine. The second were exposed in the shade, A 1 and B 1 simultaneous to the two halves of the same negative, for the purpose of demonstrating, by contrast of intensity, the superior sensitiveness of the fumed over the unfumed prints.

In the other specimens I aimed at printing all to the same intensity, that the effect of fuming may be judged of by a comparison of the relative times of exposure. On removal from the pressure frame I find the fumed prints not warmer than the unfumed, as Mr. Debenham finds them, but of a rich violet or purple, as if richly gold-toned. The prints of each series were toned all together, for the same time, in an acetate bath, and remained all the same time in the hyposulphite.

I think it necessary to state my own conclusion from these experiments, as the majority of your readers will not have the opportunity of seeing the prints. In the first series No. 1 is somewhat less intense, and rather less toned than the others, which are all as near as possible the same tone and strength; showing, much to my surprise, that a long or a short fuming makes not much difference either as to sensitiveness or other effect. In the second series with the weaker bath, the difference in sensitiveness appears still more in favour of the fumed.

The difference in time between A 1 and A 2, is accounted for by the fact that the latter was printed later in the day when the light was not so good. B 1 exposed with A 1, shows a much greater depth of printing than its fellow, as indicated by the bronzed shadows. The remaining two are very much alike in strength and colour. It is a question how far the particular salt in the paper, and the proportion of it, affects the result; this might soon be decided if the albumenizers would kindly furnish the required information.

I should feel obliged if you would, after examining the prints, state your conclusions whether they agree with or differ from mine, and if you think the experiments worth bringing before the notice of either of the societies you are quite at liberty to do so.

It is not worth while to refer to the originality of my experiments upon this subject, further than to thank the Editor of this journal for correcting the misstatement that I had been carrying out the American discovery, and thus fulfilling one of the highest offices of a journalist, viz., that of vindicating the truth, whether the matter be one of great or of small importance.

Cheltenham, March 28th, 1863.

[The specimens we have receive strikingly bear our Mr. Penny's remarks; those which have been fumed being in all cases deeper in tone, as well as having been printed in a shorter time. We shall take an opportunity of bringing them before some of the societies, and probably at the same time some experiments of our own in the same direction.—Ed.]

ON DEVELOPING THE PHOTOGRAPHIC NEGATIVE.

BY M. AUG. TESTELIN.

The photographic image is not visible upon the sensitized plate immediately after its exposure in the camera; we know that to cause it to appear, it must be submitted to particular reactions, which gradually develop it with all the requisite details.

In the collodion process we produce these reactions by means of special reducing solutions, the particular composition of which is one of the distinctive characteristics of the process.

The reducing agents most employed for developing collodion images are, sulphate of iron and pyrogallie acid, either separately or when the sulphate solution only has been employed, to make the image appear in feeble strength with a view of being afterwards strengthened by pyrogallie acid, in order to keep the picture very pure and give it more relief and brilliancy.

The sulphate of iron developing solution must be employed only in a weak state. When too strong, the development proceeds so rapidly that time is not given to watch the appearance of the image, which appears suddenly, and is immediately fogged, even before we are able to stop the reaction at the proper moment, a crisis which we can appreciate only by an attentive inspection of every part of the proof.

Employed as a dilute solution, with a certain quantity of acetic acid added, the sulphate of iron produces a gradual and less energetic development; the image appears successively in every part, clear and well defined, its contours well detached, and we can produce at pleasure more contrast or more harmony between the whites and blacks.

This mode of development has the indisputable advantage of permitting the employment of collodions reddened by iodine, and of acid sensitizing baths, the use of which is infinitely preferable. The exposure in the camera is shorter than required with pyrogallie acid, and in all cases the negatives thus produced are much superior in transparency, by the complete detail which we can obtain both in the most opaque parts, and in the lightest, and by the softness, delicacy, depth of the shadows, and the admirably modelled condition of the luminous portions.

But to obtain all these qualities, we must not seek to obtain a picture at first as intense in the opaque portions, as it is desired they should remain: for in that case we produce only hard negatives, completely black in the shadows, and without detail in the whites, an effect frequently attributed solely to the too energetic action of the sulphate of iron, while it is principally due to the too great concentration of the sensitizing baths, which, by leaving abundance of nitrate of silver upon the film, furnishes immediately so great a quantity of particles of reduced silver, which are carried in a mass to the most impressed portions of the film, where they form considerable deposits.

On the contrary, it is with very weak acid intensifying baths that the image successively appears in every part, and

if it then lacks the necessary intensity for printing positives upon paper, we can easily communicate it by a well conducted intensifying.

Returning to the preparation of the sulphate of iron developing solution, we give the proportions in which it is employed; and which are nearly the same as those employed by operators working by methods analogous to our own.

Sulphate of iron	50 grammes
Crystallizable acetic acid	...	30 to 40	"
Water	1000 "

We sometimes add to this solution alcohol in the proportion of 4 to 5 per cent. of the ferric solution. The object of this addition is to give to the developing solution about the same density as that of the argentiferous liquid covering the sensitive plate, which is saturated with the ether and alcohol of the collodion, and forms a sort of greasy film, which prevents the equal mixture of the two solutions, producing marbled spots upon the negative, due to the liquid veins of different densities, which cause a partial reduction.

In our own practice we suppress the addition of alcohol because the acetic acid suffices, acting as a moderator of the reducing action, communicating at the same time to the solution that penetrating property which facilitates the perfect mixture of the liquids.

With the solution thus composed, the image is not suddenly developed, it is only two or three seconds after its extension upon the exposed film that the parts most vividly lighted begin to appear, and the whole is developed in from 30 to 50 seconds. For we particularly recommend the stopping of the action of the sulphate of iron as soon as all the details have come out sufficiently, without considering if the negative be vigorous enough for printing with, as it is much more advantageous to give the requisite intensity to it by the intensifying processes hereafter indicated.

Until recently pyrogallie acid was almost exclusively employed for developing collodion negatives, and it is still one of the best reducing agents for that purpose: but now the employment of sulphate of iron has become so general, on account of the facility with which it is managed, and of the regularity and promptitude of its results, that pyrogallie acid serves only, it may be said, to complete the development begun with sulphate of iron.

Still pyrogallie acid is often necessary to give to certain subjects more contrast than they naturally exhibit, and where the sulphate of iron does not sometimes act so advantageously. It is on account of this property that it is preferred for the images of all objects in which the tints are black and white rather than coloured.

Under the action of this reagent the image appears almost as rapidly as with sulphate of iron, but is infinitely longer in finishing, and requires a more prolonged exposure to the light for the details to come out sufficiently.

The solution of pyrogallie acid is particularly suited to the development of images formed upon a sensitive film prepared with neutral products; it is composed in the following proportions:—

Water	500 cubic centimetres.
Pyrogallie acid	1.30 grammes.
Acetic acid	30 cubic centimetres.

When we are compelled to prolong too much the contact of the pyrogallie acid upon the collodion film, the latter at length detaches itself from the glass, causing the loss of the image, or at least a portion of the negative. This result is due to the large quantity of acetic acid the solution contains, and may be avoided by substituting citric acid for acetic acid, which also presents many advantages with regard to the negatives themselves, which are very pure and possess great transparency, only the citric acid does not communicate to the bath that greasy property which facilitates the uniform extension of the liquid upon the plate; it therefore becomes necessary, to this end, to introduce a certain quantity of alcohol. The solution is then composed as follows:—

Water	500 cubic centimetres.
Alcohol	45 do. do.
Pyrogallic acid	1·30 grammes.
Citric acid	1·50 do.

This solution becomes decomposed in the course of a few weeks, it absorbs oxygen and deposits a very light brown substance; it first assumes a light brown tint, which becomes deeper and deeper. Then, at the time of pouring it on the plate, it almost immediately precipitates the silver of the sensitizing solution adhering to the sensitized plate, and the development of the image is checked, because the molecules of reduced silver instantly group together, forming corpuscles of too large a volume for them to continue to follow the attractive force that draws them to the parts modified by the light to which they can no longer attach themselves.

(To be continued.)

STRENGTHENING NEGATIVES.

BY C. OMEGANCK.

To obtain negatives of suitable strength we must employ a developer which does not give at once all the opacity required; for if we employ an iron solution adapted to produce a finished negative at once, we incur on the one hand the risk of too strong a negative, which will give positives on paper in which the lights of the picture cannot be distinguished from the first shades. It also presents another inconvenience; when the negative produced under the conditions of a vigorous development is a little too feeble, it then becomes very difficult to strengthen it, without exceeding the proper intensity. And, lastly, in a negative feebly developed, the details of the dark portions come much better than with very strong development.

We can strengthen either before or after the fixing, or at both these periods at the same time, if necessary. The strengthening after fixing can be made by daylight, and is more easily performed, because we can better watch the gradual strengthening of the picture from the first up to the point at which it is desired to stop it, the tone afterwards remains nearly the same, a simple washing merely suffices to finish the negative, while, if we strengthen before fixing, the fixing removes a notable quantity of the opacity we had obtained.

Strengthening by means of pyrogallic acid with the addition of acetic acid and nitrate of silver, according to the ordinary formula, appears to us to merit the preference over all other processes hitherto described. The employment of citric acid, in place of acetic acid, may present certain advantages, especially in dry processes.

Strengthening by means of the salts of mercury is generally discontinued, especially when, to obtain the necessary strength, we must have recourse to sulphurization, either by hyposulphite, or by any other sulphite, for then we obtain negatives which are liable to become weaker and even to disappear altogether.

Besides, to strengthen an extremely weak negative, we whiten it with corrosive sublimate to blacken it afterwards by means of hyposulphite, or of sulphide of ammonium, it thickens so much that the delicate lines become completely obliterated.

An intensifying solution is sold at ten francs the litre which is not worth ten sous, and which, it is declared, does not contain the slightest trace of mercury. Much astonished will the photographer be if he drops a little of the solution on a clean piece of copper, to perceive it covered with globules of the fluid metal; and if he does not wish to suspect the word of the dealer, there remains for him no alternative but to believe that he has realized the alchemist's dream, and succeeded in transmuting metals.

This preparation gives much greater vigour to the picture than corrosive sublimate, without whitening it by prolonged contact. It is merely a solution of bichloride of mercury, or

corrosive sublimate saturated with iodide of mercury. It is prepared by making a saturated aqueous solution of corrosive sublimate, then dissolving a small quantity of iodide of potassium in water, and dropping it cautiously into the solution of bichloride of mercury until a red precipitate remains, which does not disappear by agitation.

Sometimes negatives are so feeble that the pyrogallic solution appears to be powerless to communicate to them the tone necessary to ensure good printing of the positives. It is not only by a too strong luminous influence, but also by a long exposure with a feeble light, that we obtain negatives that refuse to be strengthened.

In these circumstances we have for a long time employed a process which succeeds perfectly, and the negatives thus obtained have not grown weaker. The mode of operating is as follows:—

After developing and fixing, wash and cover the plate with a saturated solution of corrosive sublimate diluted with twice its volume of water, until the surface blackens; pour off the liquid, then wash the plate and cover it with the ordinary pyrogallic developing solution; replace this latter liquid by an identical quantity of fresh, but additionally this time with some drops of an ordinary solution of nitrate of silver; pour it off and on to produce the strengthening required, as in the method usually practiced.

If the first operation does not bring the desired vigour, the negative must be washed and treated anew with the mercurial solution, then with the pyrogallic solution, as before. We can in this way strengthen a negative indefinitely, the sensitive film being constantly regenerated.

The operation must be performed in a feeble light. We can replace the solution of corrosive sublimate by the compound solution (bichloride of mercury saturated with iodide of mercury). It will, however, be as well to reduce it by the addition of thrice its volume of water.—*Bulletin Belge de la Photographie.*

THE ACCELERATING EFFECTS OF BROMIDES IN COLLODION.

BY CHARLES WALDACK.*

I WROTE to you some time ago I had repeated some of my former experiments with iodized and bromo-iodized collodion; what induced me to do so was that the accelerating properties of bromide of silver were denied in several communications to the photographic journals, thus creating some doubts in my mind about the manner in which these experiments had been conducted.

The first in this new series of experiments was made three or four months ago. I made some plain collodion with equal parts of ether and alcohol, and six grains to the ounce of Beynch's alcoholic pyroxyline, an article which, as far as I could ascertain, was quite free of that peculiar organic substance which causes collodion to yield intense negatives. This collodion was rather thick, thicker than it ought to be for ordinary work, but I made it so purposely, in order to obtain a stronger contrast between blacks and whites.

Part of the collodion was iodized with $4\frac{1}{2}$ grains to the ounce of iodide of cadmium, and I added a few drops of tincture of iodine, to give it a slight tinge of yellow.

After it was well settled, I took five small bottles, marked them 0, 1, 2, 3, 4, and put one ounce of it into each.

To No. 1, I added one grain of bromide of cadmium.

To No. 2, I added two grains.

To No. 3, I added three grains.

To No. 4, I added four grains.

* We have pleasure in reproducing from the *American Journal of Photography*, this article by Mr. Waldack, who is a most careful experimentalist and clear writer. Our own convictions as to the advantages of a bromide in collodion, based on repeated exhaustive trials, have been often expressed; and we do not therefore feel bound to controvert every statement to the contrary which may occur in communications appearing in our pages; but we are glad to publish experiments so conclusive and so simply stated.—*Ed. P. N.*

To No. 0, I made no addition.

Two days afterwards these different samples were tried; the light was changeable, but as I tried two samples on one plate this was no objection.

The instrument used was a quarter-size Jamini, with half-inch stop.

The object a photographic view.

The bath was of 40 grains to the ounce, iodized and acidified with one drop of diluted nitric acid.

The developer was the ordinary iron one.

Those marked 0 and 1 were tried together on one plate; then 0 and 2, 0 and 3, 0 and 4, each time giving *about one-half or two-thirds of the proper exposure*, in order to be better able to see the difference. The result was that the bromo-iodized collodion gave each time an image more advanced than the iodized one. In the same time the iodized collodion gave an image with denser whites, the half-tones being very slightly marked. In measure also as the quantity of bromide was increased the image became less contrasted, and the details more marked. Between 0 and 3, the difference seemed to be as if No. 3 had been exposed one-third longer; 0 and 4 being tried together the effect was more striking yet.

These experiments were conducted with every possible care, at one time flowing and dripping one collodion first, at another time flowing and dripping the other.

In developing I poured the solution in the middle of the plate, so that it could not be said that on one side some of the solution was washed away.

As there is an opinion prevailing that bromo-iodized collodion is more sensitive, only when used in connection with an iron developer, I resolved while I was at it, to set this matter to the test also, and made a solution of pyrogallie acid.

I tried 0 and 3 together twice, alternating the flowing, and the same result showed itself so plainly, that I thought more trials useless.

In a pamphlet by T. C. Ponting, called "Photographic Difficulties," I had seen an assertion which I found so singular that I resolved to put it to the test also. Mr. Ponting says that with a bath containing nitric acid $\frac{1}{4}$ drop to the ounce, bromo-iodized collodion is most sensitive, but when the bath is made with acetate of soda and acetic acid, iodized collodion, on the contrary, is the most sensitive.

I made thus a solution of acetate of soda with excess of acetic acid, and added a few drops of it to my silver; that I had enough acetate of silver dissolved to saturate the bath was proved to me by the deposit. The bath was tried without filtering, both with iron and pyrogallie, with the same results as before, plain, unmistakable results, which I have here before me at the moment I am writing.

I did not follow Mr. Ponting's recommendation, *to let the bath stand several days*, but as I am in the habit of making my baths immediately before using them, I found Mr. Ponting's recommendation a little obsolete. However, as I wanted my conscience clear from all blame, I tried the same bath several days after, and the result was a foggy picture, so foggy that only traces of it could be seen, with the bromo-iodized collodion, a clear one with the iodized; of course I could not compare them.

Now, after I got through with all that, somebody to whom I communicated these results, found right off a way to account for them in the fact that collodion Nos. 1, 2, 3, 4, contained respectively 1, 2, 3, and 4 grains of sensitizing more than No. 0. I knew well enough, by experience, that his conclusions were false, that a more or less larger quantity of iodizing within certain limits has no effect on the sensitiveness; but to accommodate him, and every one who might think like him, I took another ounce of iodized collodion and added one grain more iodide, then another one, to which I added $\frac{1}{4}$ ounce plain collodion, and tried them on the same glass, with the result I expected, namely, *no difference between the two*.

A few days ago, the collodion being then over three months old, I repeated some of the experiments in presence

of Dr. Van Monekhoven, and in a bath which he had used; the results were identical with the first ones obtained.

An opinion prevailing to a certain extent is, that with pure chemicals an iodized collodion is more sensitive than a bromo-iodized one. If this is true, I must conclude out of it that I never yet had a chance to experiment with pure chemicals. Admitting this to be the fact, pure chemicals are the exception, impure ones the rule. Conclusion: work with bromide.

I think a great cause of error in experimenting with iodized and bromo-iodized collodion, is the giving too long an exposure. When such is the case, the difference between the two images is not so striking. When the plate is much over-exposed, no difference at all can be seen. I think that in these experiments only one-half or two-thirds of the regular exposure should be given.

Another cause of error in comparing developed plates together results from the use of full apertures or large diaphragms. One or two seconds cannot be so easily fractionated as so many minutes. A difference of one-eighth in a short exposure is equivalent to a proportionate difference in a long one. Now, one-eighth of a second is not appreciated, whereas one-eighth of a minute is eight seconds. If we consider the matter in a theoretical point of view, I must confess that we have not got the best of the argument.

Bromized collodion is undoubtedly less sensitive than the iodized (according to Hardwich, ten times less). How could the bromo-iodized be more rapid than either? To point to the same results in the daguerreotype process would, I think, be an error, for the two layers of iodide and bromide of silver are there superposed, whereas in the collodion process the molecules of iodide and bromide are mixed together in one layer. Without waiting thus for a theory to be found to explain this, I will continue, the same as in the past, to use and recommend bromo-iodized collodion for its superior sensitiveness, in the same time recommend it for its half-tones, and for the results it gives with baths, which with iodized collodion could not be used.

THALLIUM.

WE learn, from a lecture delivered on the 27th, by Mr. Crookes, at the Royal Institution, that, by the aid of the grant recently made to him for the purpose, this new metal is likely to be obtained in tolerable abundance, notwithstanding that a ton of pyrites only contains ten ounces of the metal. We cannot do better here than reproduce an interesting summary, from the *Athenæum*, of Mr. Crookes's paper, read at the Royal Society a few weeks ago:—

"A paper which, at the close, was pronounced by the leading chemists present to be one of the most important contributions to chemical science that has of late appeared. Since his discovery of the metal, Mr. Crookes has been engaged in further researches and experiments into its properties, and the sources from which it is derived. In the latter quest he applied to manufacturers of oil of vitriol for specimens of the pyrites burnt by them in the process, and of the deposit left in their leaden chambers; and we are glad to record the fact that the much-desired specimens were sent to him from nearly thirty manufactories. He tested also the various minerals collected in the International Exhibition, to verify his former opinion that "thallium is a very widely distributed element," and found ample confirmation. Thallium exists not only in iron pyrites, but also in native sulphur, zinc, cadmium, bismuth, mercury, and antimony ores, as well as in their manufactured products. As yet Mr. Crookes has failed to detect the "law" of the distribution of this remarkable element; but he has ascertained that it is confined to no particular country, though by no means uniformly distributed in mineral veins from the same locality. Owing to the delicacy of the test employed—the spectroscope—thallium can be detected, if present, in the proportion of only 1 to 100,000. In his statement of the physical characteristics of thallium, Mr. Crookes

shows that it has a distinct colour of its own—has no perceptible taste when bright, but is pungent and biting after long exposure to the air—that it is the softest of known metals, and marks paper as easily as lead, with a streak which changes from blue to yellow—can be compressed in a mold or die, and formed into wire by pressure—that it volatilizes easily, and is a pretty good conductor of heat and electricity—that it is strongly diamagnetic, and readily alloys with other metals. These are but a few of the principal facts brought out during the reading of the paper, which elicited approval, as much for the variety and ingenuity of the experiments by which they had been demonstrated, as for the clearness with which they were described. The paper is to be regarded as an instalment of a subject which has yet to be worked out by laborious research. It cannot be in better hands than those of Mr. Crookes; and, considering the attempts that have been made on the other side of the Channel to deprive him of the merit of his discovery, we notice, with pleasure, that a sum from the Government grant, administered by the Royal Society, has been allotted to him, in aid of the further work which he hopes to accomplish.*

We may further add, that Mr. Crookes regards thallium as belonging to the silver and lead group of metals, and demonstrated its similar reaction with hydrochloric acid, iodide of potassium, bichromate of potash, sulphide of potassium, &c. He also illustrated various very curious characteristics of the metal, amongst which we may mention the singular property of welding at the ordinary temperature of the atmosphere; a number of small pellets being placed in a tube and submitted to pressure, issued in a perfectly connected tough wire. As yet its economic value and applications have to be discovered. We do not at present perceive any probable photographic application of any of its compounds.

A SHORT LESSON IN CHEMISTRY.—No. 7.*

IN the present lesson I will give you a little information about gold and one of its salts. The leaf which is sold by the dealers in chemical drugs is not always gold; it is more frequently bronze. Of course gold leaf can always be had; and you can easily distinguish the leaf of gold from that of bronze. Take a few drops of pure nitric acid in a test tube, and by means of a glass rod introduce a piece of the so-called gold leaf—if the acid dissolves the leaf, the latter is certainly not gold; it will contain copper and other metals. As a second experiment now take a drop of the solution produced in the first experiment, and add to it a drop of ammonia—an intense blue colour will indicate the presence of copper. For your third experiment take a piece of polished iron wire and dip it into the first solution—metallic copper will be precipitated on the iron wire. In like manner, but by other experiments, any other metal might be detected. But we will suppose that the leaf was not all acted upon by the nitric acid; in this case add a few drops of hydrochloric acid, which will undoubtedly then dissolve the metal; and, since this metal is yellow, you can decide at once the leaf is gold; for there is no other yellow metal that is insoluble in nitric acid, and soluble in nitro-hydrochloric acid.

If you wish to ascertain whether a certain ring or trinket is gold, proceed as follows:—Make a streak with the ring, &c., on a piece of ground glass, or on a piece of unglazed porcelain, or wedgewood mortar; then add to the yellow streak a drop of nitric acid—if the streak is entirely dissolved by the acid, there is not a particle of gold in the trinket; if some portion of the yellow streak remains after repeatedly trying to dissolve it by nitric acid, you may conclude that there is gold in the ring, &c. If you wish to ascertain whether the ring, &c., be alloyed either with silver or copper, or with both, try the following experiments:—Experiment No. 1. Dilute the solution of nitric acid and the metal with a few drops of water, mix intimately, and then add

one drop of ammonia—a blue colour, as before, indicates the presence of copper. Experiment No. 2. Add one drop of the diluted solution to ten or twelve drops of water in a test tube, now add a single drop of hydrochloric acid—if a milkiness is produced, you may conclude that silver may be present; to be sure about this point, allow the precipitate, which is the cause of the milkiness, to settle; then pour off the supernatant liquid and wash the sediment with rain water, allow it to settle and again decant; repeat the washing two or three times—at least pour the sediment upon a clean saucer and expose it to the rays of the sun—if the colour soon changes to a violet-hue, be assured that silver is the metal.

Experiment with real Gold Leaf.—Mix together in a Florence flask, or pear-shaped glass bottle, a couple of ounces of the peroxide of manganese and the same weight of hydrochloric acid, and after the proper arrangement is made for collecting the chlorine which is produced, by means of a perforated cork and a glass tube bent twice at right angles, throw into the vessel containing the chlorine a few sheets of gold leaf, these will immediately be acted upon by the chlorine, and so energetically as to produce flame. That which is produced is a chloride of gold. In this way the chloride might be prepared; but it is prepared otherwise as follows:—Take a mixture of one ounce of nitric acid and two ounces of hydrochloric acid; this is nitro-hydrochloric acid, or the *aqua regia* of the alchemists, so called because it will dissolve the royal metals, gold and platinum. But we do not obtain from this solution of a metal in *aqua regia* a nitro-chloride, we obtain simply a chloride, and it is obtained in the following manner:—

Nitric acid is easily decomposed into its elements, or at least is easily resolved into compounds of the same elements containing fewer equivalents of oxygen, so that one equivalent of oxygen is set free and acts upon the hydrogen in the hydrochloric acid, whereby water is formed and chlorine liberated. The chlorine thus liberated combines with the gold so as to form chloride of gold; naturally by such a proceeding we have in the solution an excess of nitric acid and hydrochloric acid, which must be expelled by evaporation.

If, in this experiment, we were to use one of the coins of the country, which may contain either copper or silver as a part of the alloy, and platinum as an accidental admixture, these metals will likewise be found mixed with the chloride of gold; for instance, the silver will be recognized as a sediment which you cannot dissolve by any new additions of the *aqua regia*, but which, when separated from the solution, is easily dissolved in ammonia, cyanide of potassium, or hyposulphite of soda, showing thereby that the sediment in question is chloride of silver. The copper remains in the solution mixed with the chloride of gold.

In order therefore to get pure chloride of gold, you must either have pure gold to begin with, or you must know how to purify your gold from the silver and copper, either before solution or afterwards. There are various ways to do this. I will tell you how I proceed. I take, for instance, a gold dollar piece which I melt with three five cent. pieces in a small crucible; by this means I can get an alloy containing much more silver than gold; it contains also copper. This alloy I either hammer into a thin leaf, or pass it between a pair of steel rollers, and then dissolve the foil thus formed in nitric acid assisted by heat. In this experiment the nitric acid must be pure. The solution will be nitrate of silver and nitrate of copper; the residue, which is somewhat dark-coloured or sometimes slightly pink-coloured and metallic, is pure gold in the form of a thin film or a powder. By washing, after pouring off the nitrates, we obtain the gold pure and in a state of fine division which is quite suitable for making chloride of gold, for it dissolves in the nitro-hydrochloric acid almost as rapidly as silver would do in nitric acid alone. By evaporation to dryness in a gentle temperature and with precautions, we obtain a residue which, when dissolved in a little rain water, will compensate you in the toning process for any trouble it may have cost you.

* From *Humphrey's Journal*.

The solution of the nitrates above separated from the gold may be evaporated to dryness, dissolved in water and then crystallized. If there is not much copper in the silver used, the crystals can be employed in the formation of your bath in which you float your albumenized paper. Or you may precipitate the silver from the copper by means of hydrochloric acid, and then reduce the well-washed chloride by fusion with potassa or its carbonate.

DEVELOPMENT BY THE FUMES OF AMMONIA.

BY ALFRED VERITY.*

At our last meeting I showed you two pictures developed by the fumes of ammonia, and at the request of our Secretary, Mr. Montefiore, I have come prepared this evening to give you full particulars of the process by which they were produced.

I have been making some experiments with ammonia, which I have no doubt will be interesting to some of the members present.

The fumes of ammonia will not develop every dry plate, but will shorten the time for development of most. This I think is due to the acid being neutralized. But its use may be carried too far; that is, a plate fumed with the same strength of ammonia before exposure, as would be required to develop the same, would be slower than if fumed with weaker ammonia. One part liquid ammonia, sp. gr. 880, to ten of water I have found to work the best; but this will depend to a degree upon the amount of acid in the plate.

I soon came to the conclusion that unless a plate could be prepared that would develop by the fumes of ammonia, there would be very little gain by using it, as it left the film in a very loose state, and what was gained in time would not compensate for the chance of the film slipping from the glass. Again, the ammonia must be driven off before the pyrogallie acid and silver is poured over the plate, or it will be covered with black stains, which spoil the picture.

After many failures I have succeeded in preparing a plate possessing the following qualities:—It will keep; is very sensitive; will develop by the fumes of ammonia in four seconds, all the detail in the shadows coming out; no tendency to spots (if proper care be taken in the manipulation); is easily prepared; and gives clear pictures with every detail.

I do not think it possible to get what is called a hard negative by this process, as any process where the development is so rapid and without silver, must, I think, give a soft tone. It is my opinion the impression made by light on the sensitive film of iodide of silver is instantaneous, and only wants bringing out.

I have succeeded in developing a picture by the fumes of ammonia, 880 sp. gr., with an exposure of less than three seconds to an ordinary gaslight; not only the high lights, but the whole of the shadows were there. Caustic potash will bring out a picture that could not be brought out by fuming.

If you give a plate an exposure in the camera—not sufficient to be developed by liquid ammonia, or any other known developer—if we fume the same (getting no image), and then expose to light for a few seconds, and after this replace it in the fuming box, you will find the picture develop. This is, I think, a great proof that the image was formed, but the developer was not strong enough to bring it out, until the light had advanced it enough to be attacked by the developer. This, of course, is only useful as an experiment, as the picture must of necessity be fogged.

To those photographers who have little patience I can recommend the process as one that will enable them, in five seconds, to see the picture, which, in the collodion-albumen and other good processes, would cause them half an hour's speculation and straining of eyes to see whether the picture is coming out. There are few that have not felt this anxiety when developing the first plate after a few days in the country with the camera. But if this were the only advantage the process possessed, it would be worth little, as photographers, as a body, possess the virtue—patience.

Those who have an objection to the use of ammonia, will find that plates prepared by this process will develop quicker than a tannin plate by the regular developer—pyrogallie acid and acid silver—giving first-rate pictures.

As the eyes are more credulous recipients of information than

the ears, I will, in the course of the evening, develop two plates—giving one one minute's exposure, and the other twenty seconds (to gas); and if, from what you will see, I can induce some of the members to take the process in hand, I am sure by their improvements we shall soon have a Manchester *dry process* as good as any at present in use.

I will now give you the particulars how the plate is used:—The plates must be coated with gelatine, or some other substance, to keep them from slipping. This I do in a very simple manner. After the glasses are cleaned I put them in clean water. I take each plate and let water from a tap run over it for a few seconds: if any grease be present it shows itself at once. I make a five-grain solution of gelatine (Nelson's), as recommended by Major Russell, and filter it through paper while hot. After draining a plate for a second, I pour on the solution warm, in the same manner as collodion: this takes all the water off with it. I do the same a second time, which does for the first portion for the next plate. I then stand the plates on blotting-paper to dry and finish by heat. Nothing could be easier, and we have perfect freedom from dust, which will attach itself to the glass that has been rubbed.

The process will work with any good collodion. I have used seven commercial collodions, all of which give good clear pictures. Some were quicker than others, but there was not very much difference in the intensity of the image.

I prefer a collodion that will give a thick film; this, I find, gives a stronger image than a thin collodion. By giving a plate a coating with collodion and then drying it well, then giving another and sensitizing it, I have been able to get a picture intense enough for a transparent positive. A plate so prepared will develop rather slower, but is very sensitive—the picture first appearing on the surface, and then on the back. This is a proof that the picture is *in* the film, and not *on* the film. With three or four coatings of collodion a picture may be obtained intense enough to print from; but the cost of collodion and silver would be so great that it would not be worth doing. There is some little difficulty in coating a plate with more than two coats; but, if well dried before a fire, and a quick-setting collodion used, it can be done. A plate so prepared will take fifteen minutes in the bath, and will have a dense film of iodide of silver.

The bath I find to work the best is a thirty-five to forty grain to the ounce of water, neutral to test paper. It is quicker than one that is acid, and the pictures will develop with weaker ammonia, and quite as clearly. The principal thing in the bath is to keep up the strength—anything under twenty-five grains giving a weak picture.

We now come to the washing. This I do thoroughly. I have four dishes:—

- No. 1. One quart distilled water.
- No. 2. do. do.
- No. 3. Town water one quart, with three ounces salt.
- No. 4. Town water, with a tap running into it.

No. 1 bath will wash twelve stereo plates. I then charge No. 2 for No. 1, and put fresh in No. 1, making *it* No. 2. I coat the first plate, sensitize, place it in No. 1 bath till the next plate is sensitized, then pass it to No. 2, until I have one dozen stereos in No. 4. I then take each plate and let water from a tap run over it for a few seconds, and stand on blotting paper to drain. I then place them into a dish containing the preservative solution—six at a time. In this they stay four minutes. The solution must be kept moving by rocking the dish. From this the plates are placed on blotting-paper to dry, and before placing in the dry-plate box I dry them by heat. If they are wanted to keep more than six weeks, wash gently for a second under a tap, after coming out of the preservative bath. The salt bath may be dispensed with if they are not wanted to keep more than a month. If the plates are not dried well before putting away they will go brown in the fuming box. The plates will absorb moisture from the air, which leaves them in the best working order. I have developed plates that have been prepared over two months, and find them work well.

The exposure is much shorter than for most dry plates, which I hope to prove to you. I have taken (printed) a picture by an ordinary gaslight in two seconds, and I think, with everything in the best working order and quick lenses, it will be able to take instantaneous pictures in the summer.

Plates coated with the following preservatives will all develop by the fumes of ammonia. I will give you them in the order I have found to answer best, starting with the worst first:—Gallic

* Read at a meeting of the Manchester Photographic Society, Jan. 7th, 1863, and reported in the *British Journal*.

acid; pyrogallic acid; gallic acid and honey; gallic acid and gum arabic; gallic acid and tannin; gallic acid and grape sugar; gallic acid, tannin, and honey; tobacco, gallic acid, and grape sugar; gallic acid, tannin, and grape sugar.

The last is the one I use. It will keep good for months, and may be used over and over again. The plates I intend to develop this evening are prepared in the same solution that I prepared two months ago, with the addition of a little fresh to make up the quantity required. It is prepared in the following way:—

Tannin	200 grains
Distilled water	10 ounces
Gallic acid, a saturated solution in water	10 "
Grape sugar	2 drachms
Distilled water	5 ounces.

The grape sugar is dissolved over a water bath, and filtered through paper. Each solution is filtered separately, and then the three mixed and filtered again. I filter every time I use this. It changes to a sherry-wine colour by keeping. I keep it in the dark, with a small piece of camphor in the bottle. Both tannin and tobacco have a preserving effect upon gallic acid. The reason I prefer tannin to the tobacco (which was what I used first) is that it gives the glossy surface to the plate, which may be brushed when dry, which tobacco does not.

It may be against all the rules of photography to use a reducing agent for a preserving one; but in practice it holds good, as I have proved by experiment.

The following plates will not develop by ammonia fumes, but will by the ordinary method:—

- Protosulphate of iron and honey.
- Plain tannin.
- Gum arabic.
- Plain washed collodion.
- Collodio-albumen.

The fuming must be done in a box with a glass top, such as you see before you. The strength of ammonia I find work the safest is one part liquid ammonia, 850 specific gravity, to two of water, placed in a dish at the bottom of the box. If the plate has had the proper exposure, it will be fully brought out in two seconds; if over-exposed, in one second; if under, four minutes. A picture that will not develop in this time will not be worth much, the film turning brown on those parts not acted upon by light, and not properly clearing up in the hyposulphite of soda. Pure ammoniacal gas will develop a picture that would not come out in the above; but with properly-exposed plates this is too rapid, the picture jumping out in two seconds. Great attention must be paid to the plate while in the fuming box, if the best results are to be had, as the plate must be removed the moment the action has arrived at a certain point, which is as soon as the picture is seen through the negative, as it were on the back, with all the detail. It is first brown, then grey, and will next seem of a yellow-brown: before this yellow-brown spreads over the picture remove it.

The first plates I prepared used to fade if left in the ammonia. The ones prepared now will stand days without fading, and undergo a process of fixing, but take a long time to intensify.

To intensify these pictures any of the ordinary modes will do, if the ammonia be first neutralized. The one I have found the best is to drive off the ammonia by heat, and then use formic acid, pyrogallic acid, and nitrate of silver. Citric acid is very good for transparencies; but is very slow.

Another way I find to work very well is to pour over the plate distilled water, with a few drops of acetic acid, then add the pyrogallic acid and nitrate of silver to the same. This is very quick and will give a jet black negative. Fuming with acetic acid is too strong, and dissolves the picture if left too long.

I fix with hyposulphite of soda.

It may be interesting to some of the members to know the effect other gases have on these plates.

Oxygen: If a plate be transferred from the ammonia into a jar of oxygen, very little change takes place; but if this same plate be again placed in the ammonia, the picture will become much stronger. I have found no change in a plate placed in this gas before exposure.

Chlorine: The action of this gas on a developed plate is to bleach the image, but not dissolve it. If a plate be placed in this gas before exposure, no picture can be developed; no marked change takes place in the film; the sensitiveness is completely destroyed. I have been unable to get a trace of a picture after long exposure.

Hydrogen: This has very little effect on a developed plate. A plate will develop after being eighteen hours in this gas. One developed by ammonia will lose a little density in this gas, but is again restored by ammonia.

Nitrogen will not develop a plate. One developed by ammonia will fade if left in this gas, and will not develop again by ammonia. If a plate after exposure be placed in this gas no picture can be developed afterwards.

Sulphuretted hydrogen will not develop a plate. If a picture that has been fixed after fuming with ammonia be placed in this the image is blackened and intensified. A picture developed by ammonia, and not fixed, will turn brown and fade. A plate placed in this gas before exposure will turn brown, and the sensitiveness is destroyed. The danger of using this gas makes it unfit for photography.

In conclusion, I have to thank you for the patient way in which you have listened to a paper containing little that is new and much that is old, and have only to add, that if I have not been explicit enough on any point, I shall be happy to answer any questions to the best of my ability. I will now develop the plates; and I hope, from the discussion we shall have on them, to go away primed for further experiments.

A SHORT LESSON IN PHOTOGRAPHY.—No. 11.*

If a negative has to be varnished (and it certainly has to be varnished if a large number of impressions are required), it must be made more opaque in the lights, because the opaque parts become somewhat transparent by varnishing. The best impressions, however, are indubitably obtained from an unvarnished negative: and where but few copies have to be taken, I would advise you not to varnish the negative; with great care in the apposition of the sensitized paper upon the surface of the negative you will seldom injure the film. When an injury does take place, it is owing to friction on the one hand, and to moisture in the paper on the other, and finally to irregularities on the surface of the paper produced by unequal drying, especially by artificial heat. If the paper is perfectly flat, and perfectly dry, and laid on the negative without the slightest motion in any direction when once in contact, there will be but very little risk of damage to the film.

Experience has taught us the peculiarities of the action of light when applied to direct printing by contact. The peculiarities alluded to are as follows:—When a negative is exceedingly dense in the opaque parts, the best prints are obtained from the action of diffused light, even sometimes after it has passed through a white curtain or a white sheet; the process naturally is slow, but the effect is very pleasing, because the gradations of tone are correctly brought out; whereas, if the direct rays of the sun were to perform the operation, some parts of the prints would be bronzed long before the others had received the proper amount of actinic action.

On the other hand, if the negative is but a few degrees removed from an ambrotype, that is, if the parts which ought to be opaque are still in some measure translucent, in such a case, I would recommend you to print with the direct rays of the sun at an open window, or even by the aid of such rays condensed by means of a set of reflectors. The operation is very rapid and has to be watched with great care. The best and most agreeable prints are obtained by the former process.

I cannot easily describe to you what length of time is required in the successful operation of printing, because this will vary with the two principal things employed, namely, the light and the negative. As a guide, you may observe the following rule. As long as the paper is preserved perfectly white under the opaque parts of the negative, and when beneath the most transparent parts no bronzing has yet intervened, you may then continue the action; and you may continue it as a general rule until the highest lights are somewhat tinged, or the deepest shades begin to show signs of approaching bronzing.

* From *Humphrey's Journal*.

The paper employed for such impressions is either plain or albumenized; both of these kinds can be purchased of the *very best* quality from the best photographic establishments. Such houses always aim to have the most successful formulae in the preparation of their photographic wares, and spare no expense in obtaining such formulae. It is therefore altogether more to your advantage to buy your paper, collodion, nitrate of silver, &c., from such dealers, than to trouble yourself with their manufacture, in which you will, nine times out of ten, fail in the minutiae. With the same propriety might the shoemaker commence tanning hides, the clock and watchmakers casting wheels, or the surgeon manufacturing scalpels, as for the business photographer to waste his time and money in the grinding of a lens, the albumenizing of his paper, or the fabrication of his chemicals. Rely upon it you can buy them cheaper and better than you can yourself present them. It is well that you should know how all such operations are performed, just as we educate our children in the geography of the Celestial Empire or in the mechanism of a watch or a steam engine, although they may never visit China, or manufacture time-pieces or locomotives.

Albumenized paper is preferred by many photographers to plain paper, and I think justly so for portraits. The only difference between the two consists in the albumenized surface, which contains within itself a sufficient degree of polish to supersede the use of any varnish after the printing, toning, and fixing are complete; besides this, the surface is more uniform than that of the very finest paper. The chemical foundation in either is an alkaline chloride, which, by floating the paper on nitrate of silver or ammonio-nitrate of silver becomes converted into chloride of silver in a state of very fine division, mixed with the nitrate of the alkali employed. The latter salt modifies in a great measure the colour and intensity of the print produced, and so does the albumen.

From this circumstance we account for the different tones in different specimens of prepared paper. Some manufacturers use chloride of ammonium, others that of potassium, sodium, or lithium, in the salting of their paper; each print, on this account, will have a different tone when it leaves the printing-frame. It remains with you to select that which pleases best.

The sensitizing bath may consist simply of a solution of nitrate of silver, containing about 90 grains to the ounce of rain or distilled water, together with a drachm or two of alcohol to each ounce of nitrate of silver. But paper so sensitized is not so sensitive to light, nor is it so quickly sensitized as in a bath containing, in addition to the above ingredients, about half a drachm of ammonia. In the latter bath good albumenized paper does not need to be floated at the very most more than a fraction of a minute; in fact, 20 seconds is abundance of time; if you float the paper longer than this the albumen is very apt to be attacked by the ammonia and to be dissolved by it, to remedy which the alcohol is not altogether sufficient. As soon as the papers are thus sensitized they are hung up, as already described in a preceding lesson, by one corner and dried. When they are thoroughly dry they are ready for the printing-frame.

COMMON PRINTING.—VIGNETTE PRINTING.

Before you proceed to print, see that the glass in the printing frame is perfectly clean and altogether free from any particle of sand, which if allowed to remain beneath the negative, would almost certainly break it when submitted to pressure. Place the negative in the middle of the space with the back in juxtaposition with the glass below, that is, with the collodion film outwards or upwards. The paper is next placed upon the negative with the albumenized surface in contact with the collodion film. Over the paper lay a sheet of Canton flannel, of vulcanized india-rubber, or of any other soft material, and finally over this place the jointed lids of the frame, and fasten them down by means of the levers and clasps with which each frame is furnished.

If it were intended to print vignette fashion, you will have to be provided with vignette glasses, which are manufactured specially for such operations, and to be had of all respectable dealers. The vignette aperture can be had of any size required; it is formed of a piece of glass stained on one or on either side with a metallic oxide which is burnt into the glass. This stain, however, is a mere film and can easily be ground away of the required shape and size by the lapidary, and then polished. The external parts, being of a red orange colour, intercept or absorb those rays of light which would act upon the sensitized collodion film, whilst through the vignette opening all the rays can act almost with their primitive vigour. Such a glass, or an appendage of such glasses, is placed first on the glass of the printing frame; upon this comes the negative, and the rest of the arrangement will be as before.

The lids at the back of the frame can be opened independently of each other, which allows the half of the print to be examined whilst the other half is kept fixed on the negative, so that the relative position of parts is never disturbed by the examination of either half.

As soon as the print is sufficiently intense, remove it from the frame and place it between the two leaves of a blank book, and proceed with the printing until you have a sufficient quantity for toning and fixing. Whenever you examine the print, the operation must be performed in some corner of the room where the light is feeble; otherwise the print would be injured by an exposure where the light is brilliant.

Here the lesson ends to-day.

Proceedings of Societies.

AMATEUR PHOTOGRAPHIC ASSOCIATION.

A COUNCIL MEETING of the Amateur Photographic Association was held on March 13th, Mr. G. SHADBOLT in the chair. The minutes of the last meeting having been read and confirmed, the following members and subscribers were proposed and elected:—

The Viscountess Jocelyn	George Ottley
Thomas Bell, F.R.S.	Thomas Fothergill
A. R. Hamilton	Rev. H. B. Ingram
The Countess of Rosse	T. H. Powell
F. R. Barclay	S. W. Rivington
John Rivington	George Daglish
Henry Wood	Mrs. Perry
Captain H. Lawson	S. St. L. Blaawn
Dr. Douglas Reed	The Hon. H. L. de Boscawen
Mrs. Spottiswoode	Mrs. Gough
Miss Darby	Mrs. S. Perry
Professor Selwyn	Miss Bagwell
Col. Whitmore	H. A. Hoare
Robert Hudson, F.R.S., F.L.S.,	Professor E. A. Clayden
&c.	D. Nicholl
W. R. Hayward	M. Peaco
H. L. Dymoke	Mrs. C. S. Harris
W. G. Hunter	Capt. W. Knipe
Thomas Fenn	G. H. Hodges
Rev. E. W. Benson	

Mr. GLAISHER asked the Secretary when accounts of sales of members' prints would be made up.

The SECRETARY replied that he purposed making up the accounts of sales in June next, and explained that although the Association had been in existence nearly two years, yet that the first year had been occupied in forming the Society, and collecting the negatives, and that the publication of them did not commence until June last. It was therefore decided by the meeting that the account of sales should be made up and forwarded to members as soon after the 1st of June each year as possible.

The Secretary was instructed to prepare for next meeting of Council a list of members and subscribers who had, and who had not, paid their subscriptions, also a list showing who had, and who had not, received their allotments of prints. The proceedings of the meeting then terminated.

A. J. MELHUSI, Hon. Sec.

IMPERFECTIONS IN ALBUMEN PRINTS.

Want of vigour and contrast.—Supposing the negative to be of the proper intensity, results—1st, from under-printing; 2nd, from a too weak silver solution. In the second case the print is rod and dim on removal from the printing-frame.

The print refuses to tone.—The negative is too weak, or the silver solution too weak.

The print is red after fixing.—Under-toning.

The print has a cold, ashy blue colour when dry.—Over-toning.

The print is yellow in the lights.—1st, accidental mixture of hyposulphite in the toning bath; 2nd, use of an old fixing bath; 3rd, careless washing, the print being left too long without a change of water.

The whites of the prints are not sufficiently pure, but are grey and dirty.—1st, exposure to light; 2nd, use of ammonia-nitrate of silver in damp and warm weather; 4th, contact with ammonia-nitrate paper; 5th, use of damp flannel on the back of the paper; 6th, use of flannel impregnated by frequent use with ammonia-nitrate of silver; 7th, too long exposure to the heat of the sun.

Brown or black stains on the print.—Contact with hyposulphite of soda before fixing.

Marbled spots.—Insufficient absorption of the silver by the paper, from the silver solution being too weak, or from not floating the paper a sufficient length of time.

Red circular spots.—Air-bubbles under the print while toning.

Irregular bronzed marks.—Impurities on the surface of the silver solution.

Red comet-like marks.—Paper floated on imperfectly beaten albumen.

Black spots seen by transmitted light.—Imperfect fixation.

Mealiness.—Too weak a silver solution.

Red freckled spots all over the paper.—A form of mealiness in thick and highly albumenized paper; too weak a silver solution; try an ammonia nitrate of silver solution, if conditions of temperature will permit it.—*The Card Photograph.*

The International Exhibition.

REPORT OF THE JURY ON PHOTOGRAPHY AND PHOTOGRAPHIC APPARATUS.*

Meriting attention from the amazing popularity which it has attained, and the great impetus it has given to photographic portraiture, is the style known as *cartes de visite*, or visiting card portraits.

Photographs of a similar size and style were amongst the earliest examples of the collodion process, but were then undistinguished by any especial title. The name by which they are now known, and the introduction to the public as a distinct class, for which a furore soon began to prevail, is due, it is stated, to M. DISDERI, a Parisian photographer of great eminence, in whose hands these small portraits attain great excellence and variety.

The accounts recorded at various times of the numbers of these portraits produced in different establishments, appear almost fabulous; it may be safely affirmed that they have attained a popularity and extent of circulation altogether unparalleled in the history of pictorial art. The production of albums especially prepared for their reception, and which are now found in almost every household, has become in itself a distinct and important branch of manufacture, and even the production of scenic backgrounds and other accessories for the photographer's studio are amongst the distinct pictorial characteristics creating a separate branch of trade.

Taking precedence in this style, in the British photographic department, are the productions of Mr. H. P. ROBINSON (United Kingdom, 3147), whose card portraits possess great beauty as artistic studies, apart from their interest as portraits.

Mr. W. MAYLAND of Cambridge (United Kingdom, 3125) also claims a notice for the excellency of his pictures in this department.

Messrs. ROSS and THOMSON of Edinburgh (United Kingdom, 3148), and MELLINS of Jersey (United Kingdom, 3188), deserve notice for their examples in this style. The small pictures of ANGEAEN of Vienna (Austria, 670) are not less perfect than his larger ones, of which we have already spoken.

Many other contributors of this style of photograph display high qualities, whilst some, it is to be regretted, are shown, which illustrate how imperfectly an art distinguished generally by its truth, can be practised; a series of card pictures, by BIRNSTING, purporting to be the portraits of the guarantors of the International Exhibition, strikingly illustrates this bad eminence to which reference is made.

An interesting feature in the various displays of photographs, consists in the pictures of life size, produced either directly in the camera, or by enlargement from small negatives by means of the solar camera, or other similar appliances.

Mr. ANGEL (United Kingdom, 3032), and Messrs. SMYTH and BLANCHARD (United Kingdom, 3157) exhibit some fine enlargements.

The contributions in this style from different continental artists comprise specimens of unsurpassed beauty. M. DISDERI of Paris (France, 1461) showing some enlargements in which the perfection of definition is in every way satisfactory.

M. ALOPNE (France, 1462) also shows a series of very large heads, stated to be produced without enlargement, possessing unusual vigour, without the coarseness too often found in these large photographs.

M. NUMA-BLANC (France, 1494) contributes some very fine amplified proofs of great excellence, and are interesting from the fact that the source of illumination in enlargement was not the solar rays but the electric light.

M. DARLOT (France, 1491), to whom a Medal has been awarded for his lenses, is much indebted to them for the excellency of the large proofs exhibited by him in illustration of their powers.

M. GNEMAA of Brussels (Belgium, 358), amongst other fine pictures exhibit an enlarged portrait of the Comte de Flandres, a standing figure from a visiting card portrait, enlarged to about twelve diameters, which, for perfection and delicacy in every part, is unsurpassed by any exhibited. HANSEN of Copenhagen (Denmark, 127), Wornly of Aix-la-Chapelle (Prussia, 1435), and some others exhibit also enlarged prints which are highly satisfactory.

Another class of photographs very popular with the public, but which at a time when the art has obtained such perfection scarcely possesses the same claim to photographic excellence as those already named, are the touched pictures, or those which owe something to the finishing pencil of the artist, who corrects supposed faults, and supplies deficiencies with a pigment approaching as nearly as possible to the neutral tint of the photograph. In some instances this is not all, as the whole picture is remodelled, the photograph merely subserving as a basis for a picture in sepia or Indian ink.

Of this class are some of the portraits exhibited by Mr. MAYALL (United Kingdom, 3123), which have every appearance of possessing much photographic excellence, being very carefully worked in imitation of a mezzotint engraving by the artist.

Another section of touched portraits are those exhibited by HERBERT WATKINS (United Kingdom, 3177), by JOHN and CHARLES WATKINS (United Kingdom, 3178), Messrs. MALL and POLYBANK (United Kingdom, 3122).

Many of these are good untouched photographs; but mixed with them are many more which are worked on, not to the extent of those just described, but still sufficiently to destroy their claim to consideration as specimens of pure photography.

Amongst others exhibiting pictures of merit in this class are BASSANO (United Kingdom, 3036), BARNES (United Kingdom, 3034), H. N. KING (United Kingdom, 3109), together with others; and it may be proper here to state that it was the original intention of the Committee of Advice appointed by the Royal Commissioners to exclude rigorously all specimens of this class. The published conditions definitely stated that such pictures would not be admitted; it was decided, however, at the last moment, when a great many examples of this class were sent in, to give them a place in the department rather than leave a bare space on the walls, which had been allotted to the gentlemen who had sent such pictures as their contributions. Coloured portraiture, with the photograph as a ground work, whilst not strictly entirely belonging to the art, has hitherto been associated with it as one of its lucrative and proper applications, and some very fine examples of such are exhibited in the British department. A member of the Jury holds a prominent position, especially in enlarged portraits coloured in oil; these pictures are not, strictly speaking, photographs, but are produced by the use of a small photographic negative and an enlarging camera, the image being projected on the camera, and traced by hand instead of by chemical agency; the outlines thus obtained are subsequently finished by the painter.

Mr. KILBERS, Mr. MAYALL, and Mr. WILLIAMS exhibit also some very effective oil-coloured photographs, a great charm in which is the fact that whilst acquiring the beauties of colour they have not lost the distinctive truth of photography.

Messrs. GUSH and FERGUSON (United Kingdom, 3084), and LOCK and WHITFIELD (United Kingdom, 3115), have photographs coloured in water colours, on which the most elaborate skill of the miniature painter is expended, giving them qualities in which they rival the best-executed ivory miniatures of the past age. The coloured specimens of McLEAN, MELCHISEN, and HAYS (United Kingdom, 3120) are very distinct, and their excellency demands every praise. The picture contributed by Mr. B. R. GREEN (United Kingdom, 3051) has also distinct features of considerable merit.

Messrs. HEATH and BEAU (United Kingdom, 3090) have charming miniatures, in which the aid of colour is secured with less elaborate manipulation and a more perfect retention of the photographic character of the portraits.

Mr. A. BAOTIERS (United Kingdom, 3051) exhibits a remarkable finely-coloured miniature photographed upon ivory, and a large group tinted in water colours with great skill; he also exhibits an excellent example of what is known amongst photographers as composition groups, consisting of an assemblage of twenty-two portraits of eminent members of the Association for the Advancement of Science. The capability of the photographer's art in correctly defining groups of several persons on a large scale is limited by the powers of his lens. To meet the difficulty, a method of printing from several negatives, originating with Mr. Rejlander, is adopted. The print to which reference is made was printed at thirty-seven different operations on paper 36 inches by 24 inches. Each negative must of course be designed for its position in the picture from the first, and although each portrait may be taken without the presence of any other member of the group, the proper relation of size must be regarded throughout, so as to produce harmony in the finished pictures. The skilful blending of the separate portraits of this group into one harmonious whole is very satisfactory.

Also, associated with portraiture, a variety of photographs are exhibited, which possess great value and interest as ethnological illustrations, especially a series of Indian portraits of native tribes together with several volucres exhibited in the French department.

Allied to portraiture, and more closely trenching upon the domain of art, is the production of *genre* pictures. Of these the productions of REJLANDER (United Kingdom, 3145) and ROBINSON (United Kingdom, 3147) take first rank. In Mr. Rejlander's photographs the most remarkable feature is the perfect rendering of an idea; each picture tells its story without explanation, the models seem perfectly easy in his hand, and the artist does not seem more fettered by his camera and chemicals than he would be by his palette and pencil.

Superior in precision and excellency of the photographic manipulation, and no less excellent as artistic productions, are the pictures of Mr. H. P. ROBINSON, several of which are printed from many negatives. "Fading away," "She never told her love," and many others have obtained a world-wide reputation.

In *lanescope* and *architecture* the progress of photography is illustrated in a most satisfactory manner, as well as in the results of the wet as the dry collodion processes. The pictures of Mr. BEDFORD (United Kingdom, 3039)

* Continued from p. 120.

possess a degree of excellence beyond which it would seem impossible to go. In his productions are admirably united great artistic excellence with perfect command of his materials. His interiors are probably the finest which have ever been obtained by photography, and illustrate the importance of a cultivated knowledge in the selection of time, light, and position.

Mr. HENRY WHITE'S (United Kingdom, 3179) are perfect landscapes, strongly exemplifying the value of artistic feeling in the prosecution of the art.

Mr. VERNON HEATH'S (United Kingdom, 3091) photographs show the high degree of excellence attained by studying the manipulatory details of the process.

Mr. DIXON PIPER'S (United Kingdom, 3135) views have all those charming characteristics which give value to pictures of English landscape scenery.

Dr. HEMPHILL'S (United Kingdom, 3092) photographs relating to Irish antiquities are highly interesting.

The Viscountess JOCELYN, Sir A. K. MACDONALD, and the Earl of CAITHNESS, send contributions which illustrate that in the amateur pursuit of an elegant accomplishment results may be obtained which rival in all excellence the works of the most able of those who practise the art as a profession.

In many of the contributions of the Amateur Photographic Association the same fact is illustrated.

Amongst the contributors who practise dry photography are many whose pictures show that dry plates in skilful hands yield results equal to wet collodion. Mr. DR. SIDEBOTHAM, and WARDLEY, send illustrations of this kind, in which delicacy and softness are secured without any sacrifice of vigour and effect.

Without entering into lengthy detail or comparison where so much excellence exists, the names of ROGER FENTON, FRITH, STUART-WORTLEY, D. CAMPBELL, LYNDON SMITH, B. B. TURNER, and others, may all be mentioned as admirable illustrations of the excellence which has been attained in the branch of landscape photography.

(To be continued.)

Photographic Notes and Queries.

SPOTS IN DRY PLATES, &c.

DEAR SIR,—In reply to Mr. Branfill's letter in the NEWS of last week about Spots on Dry Plates, I have little hesitation in saying that they are caused by the albumen.

When I first began Major Russell's excellent tannin process I always used gelatine as a preliminary coating; seeing however somewhere a recommendation that albumen should be used for that purpose, I carefully tried it, both plain and iodized, when spots of imperfect development at once appeared, besides a great tendency to stains. On returning to the gelatine, they did not present themselves, nor have I ever been troubled with them since.

During the last month or two I have been making experiments for the purpose of obtaining rapid dry plates, and I am glad to say that I have, by a modification of the tannin process, succeeded in getting a fully exposed negative with "Ross's" single stereo lens of 4½-inch focus with fixed stop (two-tenths inch) in ten seconds, the detail well out and the clouds beautifully rendered.

I purpose attempting to take an instantaneous street view, so soon as I have an opportunity on a favourable day, and if successful, will send you a print.—I am, yours truly,

JOS. T. HURST.

Mirfield, March 30, 1863.

SPOTS ON DRY PLATES.

DEAR SIR,—The principal cause of spots on dry plates I think arises from the bad quality of the glass. I have had many samples of prepared plates brought for examination, afflicted with this disease, and in ten cases out of twelve trace the mischief to the glass. In my own practice I am not troubled with it since adopting the following simple

Rule.

Take a few plates from the packet, or stock of glass intended to be used for dry plate photography, clean them by the method generally used, breathe on each plate, closely observing whether any spots appear, if so, such plates are worthless. But should the breath dry off, leaving the plate clean, proceed with the test. The cleaned plates are to be placed in the plate box and left for a week or so; if after that period spots are not produced by simply breathing on the plate, they may be used with safety. I find it necessary to try every description of glass, as none is free from this defect, which defect arises in the annealing oven. Another, but not frequent cause, by mixing an old powdery collodion with a new and glutinous one, and using it too soon after mixing.—Your obedient servant,

H. R. NICHOLS.

2, St. Jude Street, March 28, 1863.

Miscellaneous.

THE MOON PIRACY.—We recently published an abstract of a correspondent between Mr. Warren de la Rue, Dr. D'Orsan, and others, respecting an alleged piracy by the last named gentlemen of Mr. De la Rue's photographs of the moon. Some further correspondence has transpired without anything being elicited to establish the originality of the photographs in "Our Satellite." Dr. D'Orsan finally entrenching himself behind his dignity will "give no reasons on compulsion, though they were plentiful as blackberries." The *London Review*, in a caustic article on the subject, supplies some evidence of Dr. D'Orsan's capabilities of literary appropriation as illustrative of a possible similar propensity in scientific matter, and gives the following passages in juxtaposition, the first from Dr. Chalmers' Sermons, edited by the Rev. William Hanna, published by Constable, Edinburgh, and Hamilton and Co., London, 1855, vol. iii. page 20:—"Who can question it? What is seen may be nothing to what is unseen, for what is seen is limited by the range of our instruments. What is unseen has no limit; and though all which the eye of man can take in, or his fancy can grasp, were swept away, there might still remain as ample a field . . . which the Divinity . . . may have peopled with innumerable worlds." From D'Orsan's "Our Satellite: or, Selenography according to the present State of Science," Part I., page 17, published 1862;—". . . For who can question it? What is seen is nothing to what is unseen; for what is seen is limited by the range of our instruments. What is unseen has no limit; and though all that the eye of man can take in, or his fancy can grasp, were swept away, there might still remain as ample a field as ever, which the Deity might have peopled with innumerable worlds." The *London Review* adds, "The remarkable similarity of these passages may be accidental. But considering there are many more examples, if M. D'Orsan should hereafter prove himself innocent of having taken to himself words and views that belonged to others, it will still have to be recorded as an inexplicable psychological fact that he thought exactly like Chalmers, and photographed exactly like De la Rue. There is but one course open to M. D'Orsan. Let him at once state the dates on which he took his photographic views—if he ever took them at all; let him say where they were taken, with what telescope; and these three data given, the scientific knowledge possessed of this particular subject is such, that the truth or falsity of any statement could be made intelligible to every child in the kingdom. If he has been guilty of copying, let him boldly aver it, and render De la Rue the justice that is due to him. For proving his right no testimony of witnesses is required, no challenges nor inspections are needed. But if M. D'Orsan refrain or hesitate to speak, the conviction in every competent mind will be dead against him."

PHOTOGRAPHIC ILLUMINATIONS.—In connection with the important part photography has played in the late public rejoicings, its application to the purposes of illumination was not the least interesting. On the night of the 10th many of these were displayed, but most notable was that at Messrs. Carpenter and Westley's, opticians, in Regent-street. It consisted of a series of portraits of the Royal Family, as dissolving views. The portraits were coloured photographs, surrounded with appropriate wreaths of flowers, and illuminated by the oxyhydrogen light. The subjects comprised the Prince of Wales; the Princess of Wales; the Queen; the late Prince Consort, &c. The portraits were followed by views of the Royal residences—Windsor Castle; St. George's Chapel; Osborne House; Whippingham Church; Balmoral; the Horse Guards; &c. The exhibition, which commenced at seven p.m., was continued till two a.m., and, at this latter hour, the crowd was as great as it was at eleven. The spectators never numbered less than from 8,000 to 10,000 at a time, and the way was completely blocked from Piccadilly down to the Club Chambers, Regent Street, and as far down Jermyn Street as brought the exhibition within eye-shot, and the loyalty manifested by the spectators was enthusiastic; several times they burst out spontaneously with the National Anthem, and when the words—"God bless our widowed Queen," were exhibited, dissolved into a portrait of the Queen herself, which was again dissolved into "Albert the Good," with the lines from Tennyson's Ode:—

"Oh silent Father of our Kings to be,
Mourning in this golden hour of jubilee"—

the murmur of mournful sympathy which ran through the immense assembly was eminently touching. When a portrait of the late Prince Consort himself followed, the cheers with

which it was greeted were enthusiastic. Among the miscellaneous series was a portrait of Garibaldi, which was received with shouts of delight. So orderly was this vast assembly, that "Good Night" being put in at the very moment when the pressure was at its highest, the thousands who had caused a dead block instantly dispersed, having first given three cheers for Carpenter and Westley. It is calculated that this singular and most attractive exhibition was witnessed by upwards of 200,000 persons.

Talk in the Studio.

ENAMEL PAPERS.—We have received from Mr. J. Spencer, of Enoch Square, Glasgow, an intimation that he is the agent for the enamel paper of which we had recently occasion to speak in very high terms. There is, however, some doubt in our minds as to the identity of the paper. The paper for which Mr. Spencer is agent, is, he states, prepared by Schering, of Berlin, who exhibited some very fine photographic chemicals in the International Exhibition. That which we tried we received from Herr Paul Liesegang, Editor of the German journal; but as his father is, we believe, connected with the preparation of photographic papers, it is probable that the paper was prepared by him and not Schering. Mr. Spencer is, then, the agent for an enamel paper, which may be as good as that on which we reported, but which at present we have not tried. We shall probably report on it on receiving a promised sample. Messrs. Johnson and Matthey are Mr. Spencer's London agents.

AMATEUR PHOTOGRAPHIC ASSOCIATION.—The firm of McLean, Melhuish, and Co., having dissolved partnership, the offices of the Amateur Photographic Association will henceforth be at the establishment of Mr. Melhuish, the Secretary, 12, York Place, Portman Square.

PHOTOGRAPHS OF THE ROYAL RECEPTION.—The preparations made by many photographers for photographing the various phases of the royal procession on the 7th, turned out in the majority of instances comparatively useless, from the unfavourable nature of the light. The best we have seen are those of Mr. Blanchard, at Gravesend. These comprise the *Victoria and Albert*, the *Raceon*, the *Black Eagle*, the *Emerald*, and other vessels, decorated from stem to stern with flags, and some with yards manned. They are soft, pleasing pictures and pleasant memorials of the occasion. An interesting view of the triumphal arch and waiting crowd at Gravesend was obtained by Messrs. Le Beau and Rust, of Bayswater. Mr. Rolfe, of Graecelureh Street, obtained some views of King William Street and London Bridge during the procession, but the light being insufficient for instantaneous work, these are under exposed.

To Correspondents.

- A. B. C.**—We cannot decide certainly the cause of the stains on your background from seeing the print, as such stains might occur from a variety of causes, you should state their appearance on the negative, and at what period they occur.
- J. H. S.**—You may without impropriety mix the two collodions of which you speak. A bath prepared for bromo-iodized collodion and iron development will probably contain nitric acid, which is not desirable in a bath intended for pyro development, and will probably cause the want of intensity of which you complain. Add a little bicarbonate of soda to neutralize the nitric acid, if you find you cannot get intensity without; but we should recommend you, for portraiture at least, to stick to iron development. We shall publish next week a new intensifier, which will, probably, help you.
- J. HAWKE.**—The definition in the prints referred to certainly does not exceed that of the prints received, nor are yours inferior in brilliancy to any we know.
- F. L. G.**—You may repair your glass bath by the aid of marine glue without hesitation. It will not act on the solution injuriously. We have cemented the ends of dippers on with this material, and used them for years without disadvantage.
- G. M. Amsterdam.**—The double sulphate of iron, to the use of which a great impetus has been given by the experiments and recommendation of M. Meynier, was first suggested by the PHOTOGRAPHIC NEWS, and is the salt described on page 374 of our last volume.
- CUMBERLAND.**—A print being too dark in the face when it comes from the pressure frame may arise either from over-printing, or want of vigour in the negative. In your case, probably, the latter. Your negative, perhaps, is too thin—lacks deposit. You require a much denser deposit of silver on the lights of a negative than on a collodion positive. Try to procure from some more experienced photographer a sight of a good negative; or, better still, the possession of one, as a guide. You will thus save yourself many disappointments in working to find out the right thing.
- GEORGE WHARNCLEIFFE.**—Various articles on plain-paper printing have appeared in our pages. You will find succinct instructions on p. 405, Vol. iv., of the PHOTOGRAPHIC NEWS, under the head, "Dictionary of Photography." We should recommend you, however, to use the process with resinized paper, as minutely described in our columns by Mr. Cooper. With all the general characteristics of plain paper you will obtain greater richness and vigour,

A CONSTANT SUBSCRIBER.—We do not know the constitution of the collodion in question; but, in all probability, it will still answer your purpose. Try it first for a wet plate, and ascertain if it have lost its sensitiveness.

2. Some operators excite both the collodion film and the albumen film in the aceto-nitrate bath. **3.** It will, probably, be a little slower; but, otherwise, we see no disadvantage. **4.** If you use ground glass, on which to print your transparencies, by all means use the plain side. It is customary, and for some reasons better, to use plain glass, and back with ground glass or a dead varnish. **5.** As the human eye sees a little more of the right side of an object with the right eye, and of the left side with the left eye, you must mount your slides in accordance with this law, i. e., you must give a little more of the right end of the right half, and of the left end of the left half. A bluish-white eard will not give a good effect to the print mounted thereon.

W. L. NOVEAEE.—Thanks for your communication. We shall be glad to learn your further experience with the developer, and also to see the specimens.

JUSTITIA.—So far as we can judge from a hasty inspection of your model, your glass house is exceedingly well arranged, and ought to permit very fine effects. In order to judge satisfactorily we ought to have some illustrations of the defects complained of to examine as well as the model. We will answer more fully in our next. In the mean time send us a few of the defective prints.

J. S. II.—So far as we can understand the defect you describe, it appears to arise from the use of an unsuitable collodion. Either an older sample or one with a more powdery and permeable texture would probably answer better. With Keene's process, we should recommend you to try his collodion.

SUBSCRIBER T.—The acetate of soda and gold toning bath should not become black; nor have we known it do so. We have seen it become purple, which indicates that some cause is in operation reducing the gold to a metallic state, and of course spoiling the bath. **2.** We do not remember such a table of a general character. **3.** The presence of nitrate of soda in a solution of nitrate of silver does not appear to produce any injurious results. It is of course accumulating in either negative or printing baths where sodium is the base of the iodide or chloride used. **4.** Stains caused by hyposulphite of soda coming into contact with the print before fixing cannot be removed.

CHARLES AUSTRONIUS.—We do not clearly understand what you mean by the "gas-light process." There is no method of producing negatives by gas-light. Transparencies may be printed by superposition by gas-light; but it is not sufficiently powerful to give a picture by exposure in the camera.

WM. FOX.—The address of Dr. Diamond is Twickenham House, Twickenham. Mr. Henry was the gentleman in charge of the Exhibition as curator. His address is, we believe, 78, Hatton Garden. Your eards are very good. There is, however, one point worth modifying: character figures like "Happy as a King" should not be seen against a smooth, clean, light background, as though standing for a portrait. Either a suitable suggestive pictorial background is desirable, or a rough wall, or a background broken into irregular masses of shade.

AMARANTH.—It is possible to produce an enlarged negative from a small one; but it requires skill and experience. There is generally some slight loss in the enlargement; but in skilful hands very little. Of course the less amount of enlargement, the less probability of loss in the definition. If the small negative be very perfect, and the enlargement be managed with judgment, a negative magnified, say six diameters, may be produced to give good results.

TRAVELLER.—The Photographic Exchange Club is still in existence. The address of the Secretary is F. Howard, Esq., 10, Lansdowne Road, South Lambeth.

PROS.—Pinholes may proceed from a variety of other causes besides the condition of the bath; but if you are satisfied they proceed from it, add carbonate of soda until there is a slight precipitate, and then sun the solution, which will probably reduce the foreign matter present, which causes the abnormal action.

GEORGE QUILTER.—If you forward one of the printing-frames you mention, we shall have pleasure in noticing it.

A. R.—There is no work published containing the details you require, but they are scattered through many articles in our pages. Mr. Osborne's article on photolithography, on p. 484 of our last volume, contains much practical information on the subject. Mr. Postlevin's work on printing without the salts of silver also contains some account of it.

G. H. C.—It is better always to wash between toning and fixing, although many who use the bath of acetate of soda first dispense with such washing. **2.** In using bichloride of mercury and iodide for intensifying, the yellow colour depends more on the strength or time of application of the mercury than of the iodide. If the mercury has acted too long, a very weak solution of iodide will turn the film yellow at once; but if the mercury be allowed to act but very slightly, you may apply a one-grain solution of iodide for some minutes, increasing the intensity without producing the yellow tint.

THOS. JOHNS.—The plan is good, but if the light be increased a little at the top it will be better. See our remarks a few weeks ago on the subject, and Mr. Rejlander's in our present number.

A. WOOD.—The illustrations of your proposed method of inking are very interesting. So far as we can judge there is less difficulty in getting half-tone on the stone than in printing it. But we hope by the aid of skill and perseverance that both will yet be done. A correspondent asks if you will detail the whole of your operations?

AMMONIA FUMES IN PRINTING.

THERE are some singular discrepancies of experience in connection with this process which require clearing up before it can become of practical benefit to photographers. Our readers have already had some record of failures in connection with it; but, with a promised improvement in the production of photographic prints, we are unwilling to allow a few failures to stand in the way, or condemn the plan as entirely useless. At present the experience is singularly conflicting, and we wait for further and more definite information before we can arrive at a decision on the question.

In our last, we gave a communication from Mr. Penny, of Cheltenham, in which he detailed his experiences, which were very strongly in favour of the fuming. Its effect, as illustrated in the specimens we received, appeared to be a great increase in sensitiveness, and a greater richness and depth of tone; the same treatment in toning giving decidedly greater depth. This experience coincides with that of various American authorities who have given opinions in favour of the process. The experience of some other operators, however, is not only opposite, but is very anomalous and varied. Mr. Debenham, who stated the results of some experiments at the Photographic Society last month, found, absolutely, no difference in the final result between the paper which had been fumed, and that which had received no such treatment. Mr. Hughes, in detailing to us the results of his own experience, described the fumed paper as assuming a greyish-blue tint in the pressure frame, and retaining that colour, more or less, whilst toning, fixing, &c., and after it was finished; the print being neither so warm or so vigorous as others from the same negative printed and toned in the usual way. We have recently been trying some experiments ourselves, and we meet with results, in many respects, decidedly the opposite to these; but still, in our estimation, a failure. We will detail exactly our operations.

We used Saxe paper, highly albumenized, and salted with seven grains of ammonium and one of sodium to the ounce, and which, by the ordinary treatment, gave us very good results. This was excited on a bath originally neutral and sixty grains to the ounce, but reduced by working to a little under fifty grains; having just been decolorized with a little chloride of sodium a slight trace of nitric acid was set free. Sheets of paper excited on this bath were divided, one half fumed, and the other left as it was. The fumed half and the other half were printed together on halves of the same stereoscopic negative. The fuming was effected by placing a saucer containing a little of the strongest liquor ammonia in a box, to the lid of which the sensitive paper was pinned. The first floating of seven minutes slightly attacked and disintegrated the albumen. Subsequent fumings of the same duration and of about five minutes did not show any such result. The effect in printing was altogether different to what, from the experience of others, we had been led to anticipate. In the first experiment the fumed paper required an exposure of about

one-fourth longer than that which had not been fumed. It printed much redder, and with more contrast or brilliancy, and these characteristics continued throughout subsequent operations. When toned in the same acetate and gold bath, it coloured a little more slowly, and remaining in the bath for the same time, as also in the fixing bath, final washings, the finished print is redder, lighter, and possesses a little more contrast than the other half which had not been fumed. Other experiments were similar; in some cases the amount of sensitiveness seemed equal between the fumed and the unfumed paper; but in all cases the tone was redder in the pressure frame, and continued so to the end of the chapter. In some cases there was a little more contrast in the fumed specimens, but in no case either greater sensitiveness or depth of tone.

We must confess that however promising some of the results may have appeared, we fear there is too much uncertainty in the very nature of the process to give promise of much practical value. In fuming we have no means whatever of arriving at certain or uniform results. Whatever the action of the ammonia may be, we have no means with such a process of fixing the exact extent of the action or the amount of the combination. Even if the same time be given to each sheet, the result must vary for the strength of the ammonia is constantly changing by the evaporation. The presence of ammonia fumes in any part of a photographic establishment, is moreover scarcely desirable. If the good were certain and definite, this might doubtless be got over; but we fear that until the conditions of success are more accurately defined, tempting as the promise of perfect prints may be, the fuming process will not prove of much practical value to photographers.

PHOTOGRAPHS IN PRINTING INK.

WE have recently been favoured by a visit from Mr. Pouncey, when he showed us some specimens and made some explanations which give a more specific meaning to the term "photographs in printing ink" than it has seemed to possess in a recent correspondence which has appeared in the *Times* and some portions of the photographic press. By the use of this term Mr. Pouncey does not simply mean prints from blocks obtained by the art of photography, as in Herr Pretsch's productions, nor photolithographs or photozincographs, nor even the photographic transfer produced in printing or other greasy ink; but positive prints produced direct from the negative in the compound of carbon, oils, and varnish, known as printing ink.

The mode is the subject of a patent, the specification of which will not be published for a few months. We are at liberty to say, however, thus much of the method of operation. A suitable photographic paper is covered by means of a brush with a preparation of printing ink containing a salt sensitive to light, and affected in the same way as the bichromates. This is ready for exposure under a negative in a quarter of an hour, or it may be kept without deteriora-

tion for months. The time of exposure varies of course with the quality of the light and the character of the negative; but generally exceeds, somewhat, the time required by a silver print.

The whole surface of the paper being black, the progress of printing cannot be seen as in the ordinary process, but may be ascertained by other methods, of which there are two or three available. When the proper exposure has been given, the print is placed in a solvent of the ink, which dissolves and removes the whole of that which has not been acted upon by light, leaving the photograph with its blacks in printing ink as though it had been produced by the printing press.

This is somewhat similar in principle, it will be seen, to some of Mr. Pouncy's early experiments in the carbon process, the whole paper being covered with the black pigment in combination with a salt which serves as a mordant under the influence of light.

It will doubtless occur to many that it will be difficult to obtain perfectly clean lights by any process in which the white paper has once been covered with a black pigment in a greasy vehicle. This, Mr. Pouncy assures us, is purely a question of material and manipulation. In the specimens we have seen there is perhaps a little to be desired as regards colour, a slight tendency to degradation in the whites being manifest; but in many respects they are very satisfactory and full of promise. They are subjects from nature, and the half tone is very perfectly rendered, whilst the shadows are deep and transparent, possessing in this respect a great advantage over most of the photolithographs we have seen. We shall look with interest for the further development of the process.

HOW TO PRINT IN SKIES FROM SEPARATE NEGATIVES.

BY WM. L. NOVERRE.

Now that white skies are going out of fashion, and photographers do their best to obtain either clouds or a tinted sky, the description of a method for producing such results may be of use to those unacquainted with it. Most of the good photographs in the last exhibition of the London Photographic Society had clouds or a tint on the sky, and no one having seen such productions can feel satisfied with a photograph having a white sky or rather no sky at all. The method about to be described will be found simple and effectual if the directions are carefully followed out.

In printing in skies from cloud plates a print must first be taken of the building or landscape about as dark as it is intended to remain after toning and fixing. Examine it on removal from the pressure frame, if the sky is white and free from spots, the negative requires no preparation; it may however happen that the sky prints through, or that there are spots and markings on it, in this case the sky must be cut out with a pair of scissors to within $\frac{1}{4}$ th of an inch of the outline of the picture; this will form a mask for the sky; a mask must next be cut for the landscape, making it rather smaller by cutting it $\frac{1}{4}$ th of an inch within the outline. These masks must be exposed to the light till they are blackened, they are then washed to remove the free nitrate, and dried. We now gum the mask on to the sky on the varnished side of the negative, so that there will be $\frac{1}{4}$ th of an inch left between the edge of the mask and the outline of the landscape; this interval is to be filled up with Indian ink laid on with a camel hair brush. It is convenient to keep some mixed up pretty thick with water in a bottle; it is then always ready for use. To apply the Indian ink, hold the negative upside down between the eye and the light, then trace round the outline on the varnished side. If the Indian ink is thick enough, one coating will be sufficient. The addition of gum would give the ink more body, but it is liable to crack and pull off the negative after a time. The negative is now ready to print from; this is done as usual; on removal from

the pressure frame the sky should be white and free from spots. We must now completely mask the landscape, leaving nothing visible but the white space above, on to which the clouds are to be printed. To do this, take the mixture of Indian ink and with a small brush paint over about $\frac{1}{4}$ th of an inch within the outline of the picture, taking care not to allow the brush to touch the white part of the print, as it would leave a white mark in the finished picture. Should the brush happen to slip, do not attempt to wash off the paint, as doing so would produce a stain on the sky by removing the free nitrate. Not painting quite up to the edge will not signify, and will be scarcely perceptible in the picture when finished. When the painting is done, lay the paper mask on the landscape, allowing it just to overlap the lower edge of the paint, gum it on either side to the part which will be trimmed off, next lay the sensitized side of the print on the sky plate, hold them up between the light and the eye to ascertain that the right part of the plate will print on to the picture, place them carefully in the pressure frame and print as from an ordinary negative; on removal from the frame place the print in a dish of water to remove the free nitrate and the Indian ink; as soon as the gum has become soft, remove the mask and put by for the next print. The Indian ink may be easily removed with a paint brush, or by gently rubbing with the finger; after proper washing the print will be ready for toning, and if the operation has been carefully carried out no join will be seen between the outline of the landscape and the sky. The masking, &c., must be done in yellow light or by the light of an ordinary lamp, which is to be preferred for laying on the Indian ink. Should there be any white spots on the finished print from the brush having been allowed to go beyond the outline, they must be touched out with water colour.

A photographer having no cloud plates may produce a tint on the sky, which has a remarkably pleasing effect, in the following way. The negative must be prepared in the manner directed for printing in clouds; a proof is then taken, and when at the proper depth remove it from the pressure frame, mask the landscape exactly as described for cloud printing, lay a glass plate over the print to prevent it shifting about, place a piece of cardboard rather larger than the print over the plate, take this arrangement into the light, or sun, if it shines, place it on the ground or table, move the cardboard screen backwards and forwards from the edge of the landscape to within a short distance of the upper edge of the print, an evenly graduated tint darker at the top and getting fainter as it approaches the horizon will be the result. The print can afterwards be treated as in the case of printing in skies; this tint can often be obtained without using the Indian ink, the paper blind being placed a little over the outline of the subject, it need not be gummed to the print as the glass plate will prevent its moving. In sunning down, the screen must not be allowed to come below the mask, or there will be a sharp edge following its outline. It is only in the case of a subject having a very irregular outline that the first plan need be resorted to. From the description I have given many may be discouraged by its lengthy description and apparent complication to attempt the process, it will, however, be found very simple in practice and the effect produced will amply repay any trouble that may be expended on it.

The negative, when once prepared, will do for any number of prints, as likewise the paper masks; these may be numbered the same as the negatives, and kept between the leaves of a black book, the pages being numbered consecutively, and with corresponding numbers, so that any blind may be readily found when required. The line of paint round the print does not as a rule take more than about five minutes for a 10 by 8 print, and as the negative is not required any more, another proof may be printed from it whilst the first is having the clouds printed on to it. The process of sunning down may be used to produce even backgrounds on portraits when from any cause, such as from their having been taken in the open air or otherwise the background is

defective; in this instance the tint should be light over the head and darker as it approaches the feet. The above method of masking might be applied with advantage to composition photographs, we should not then see the line of paint round the figure which has to be stippled in with much care and labour after the print is finished, and which may be noticed in many composition pictures.

25, South Street, Park Lane.

REPORT ON THE NEW FIXING AND DEVELOPING AGENTS.

PRESENTED TO THE FRENCH PHOTOGRAPHIC SOCIETY BY
M. DAVANNE.

At the meeting of the society held on the 9th of January last, M. Meynier presented two salts applicable to photography: the one as a developing agent to replace the ordinary sulphate of iron, the other as a fixing agent to replace hyposulphite of soda. A Committee consisting of MM. Périer, Bayard, Girard and Davanne was appointed to make practical experiments on the employment of these salts, and I have now the honour of giving you an account of the experiments made by the Committee.

The new developing agent proposed by M. Meynier* is the double sulphate of iron and ammonium; previously known to chemists and described by Berzelius together with the analogous salt of iron and potassium: but hitherto it has not been employed in photography.

The Committee first tried if the proposed salt developed negatives properly, and it was unanimously agreed that the photographic picture was developed very pure and soft under the action of the double sulphate. This agent may therefore replace both sulphate of iron and pyrogallic acid: but as to the question which developer is to be preferred, there was considerable diversity of opinion, and in fact it is a difficult if not an impossible question to solve, that of knowing which among several products giving good results is to be preferred: for it depends upon a host of different circumstances, and the best must be replaced at a given moment by another, if the conditions are no longer the same: thus when a photographer finds his negatives too grey and inclining to *fog*, it will be advantageous to employ the double salt proposed by M. Meynier: but if with the ordinary iron bath the negative comes pure, the greater purity due to the double salt will give a dry aspect to the picture.

The inventor of the process gives the following formula:—

Double sulphate of iron and ammonium	5 parts
Water	500 "
Pyroligneous acid	20 "
Alcohol	10 "

In our experiments we found the quantity of pyroligneous acid too large, and we have been able to reduce it one-half without inconvenience; that is, 10 parts acid to 100 parts water. The addition of alcohol is not absolutely necessary: it is useless, if the developer flows over the glass well; but, if it forms a greasiness upon it, alcohol must be added, little by little, until equilibrium is established.

The double salt is very easily prepared: it suffices to take 2 parts of sulphate of iron and 1 part of sulphate of ammonia, and dissolve them in a porcelain dish by means of 4 or 5 parts of warm water. When completely dissolved, the solution is filtered and left to crystallize: the mother water can be employed in making a second solution. The crystals drained and dried upon bibulous paper are ready for use. The salt is preserved in a solid state in a well stoppered bottle: the solution may be prepared a long time in advance; it finally acquires a brown tint, which does not alter its properties in any respect.

M. Meynier has presented us with a new re-agent, endowed with valuable properties: it remains only for operators to learn the use of it.

The second salt proposed by M. Meynier offers still greater interest, for he assumes to replace by sulpho-cyanide of ammonium, the hyposulphite of soda, which is the cause of so many spots and much fading. The committee thought that by leaving to MM. Davanne and Girard the theoretical researches which belong to their general study of positives, they could especially occupy themselves with the practical side of the question, and their experiments, as yet but few, in consequence of the deficiency of material, were all in this practical direction.

We first undertook to fix some negatives, and we satisfied ourselves that well washed negatives, upon which a saturated solution of sulphocyanide of potassium is poured, are fixed almost as rapidly as with cyanide of potassium; pouring off the solution, we wash the negative, and if the washing causes a white precipitate to appear upon the plate, it is sufficient to quickly pour a second quantity of the fixing solution in order to remove it completely. During this operation, a light sulphurous odour may be disengaged, arising from the mixture of the acidulated sulphate of iron with the sulphocyanide of ammonium: but this odour will not appear if the negative has been well washed, nor if the liquid does not drop into the same dish as the sulphate of iron. A rapid washing concludes the operation of fixing.

This method of fixing presents the advantage of replacing so dangerous a substance as cyanide of potassium by a body which we have reason to believe is inoffensive—and of substituting, for fixing with hyposulphite of soda, which always acts slowly, and demands the greatest precautions to avoid spots in the subsequent preparations—a much more rapid fixing, and without giving spots, even when a considerable quantity of the salt adheres to the fingers. The fixing of paper positives, which we carried on simultaneously with a fixing with hyposulphite of soda, has given us results comparable with the latter.

The proofs, a little deeper toned than usual, and washed, were placed in a bath of sulphocyanide of potassium, strength 30 per cent., then washed. In consequence of a chemical decomposition, this washing immediately gives a white precipitate of sulphocyanide of silver, part of which remains on the proof: this must be removed by a second fixing in another solution, also at 30 per cent. After these two fixings, the washed proofs exhibit an aspect exactly identical with those fixed with hyposulphite of soda. We must advise photographers that all the operations of fixing with sulphocyanide of ammonium must be conducted in dishes which have not been used with hyposulphite of soda, otherwise the proofs will be immediately spotted and spoiled.

Your Committee has not entered upon the economical question, not but that it is a question of great interest, but they thought it was quite secondary to that of the probable permanence of the proofs; and, moreover, from the moment that a substance enters into general consumption, we may leave it to the talent and interest of manufacturers to reduce the cost as quickly as possible. While on this subject, we may remark that pyrogallic acid, at first ten shillings the drachm, is now twopence. Besides, many large manufacturers have assured us that this new salt can be sold nearly as cheap as hyposulphite of soda.

Your Committee is therefore of opinion, that as sulphocyanide of ammonium may replace hyposulphite of soda in fixing positives, without their exhibiting any appreciable difference, that they are justified in recommending photographers to introduce this salt into their daily practice; it is only by operating on a large scale that the advantages and possible inconveniences of this salt can be appreciated, and which the laboratory experiments may not have sufficiently made evident.—*Bulletin de la Société Française de Photographie.*

* The use of the double sulphate of iron and ammonia was first suggested by the PHOTOGRAPHIC NEWS.—See vol. vi. p. 374.

ON THE MOST RECENT SPECTRUM DISCOVERIES.

BY PROFESSOR W. ALLEN MILLER, F.R.S.*

THE subject of the lecture, the learned Professor said, was, perhaps, the most extensive and fascinating which presented itself to scientific men. On the present occasion he intended to limit himself to but a few of the interesting discoveries made in this great field of research, and hoped he should not be considered egotistical if he referred to his own experiments. Among the rays emitted by the sun there were three kinds, interesting as endowed with special action—those which conveyed heat, light, and chemical action. With heat he should have but little to do on this occasion; about light he had something to say; but he was now principally concerned with the rays which manifested themselves by producing chemical action. It was well known that transparent substances did not transmit all these rays with equal facility. Glass was only imperfectly transparent to the chemically active rays, which were found in the most refrangible rays of the spectrum, heat rays being in the least refrangible portion, and light occupying the middle place. It had been found that rock crystal was one of the few substances which perfectly transmitted rays, those highly refrangible, which glass absorbs.

The Professor then showed that some kinds of light were without chemical action, the light from a mixed air-gas flame possessing scarcely any, while that from an ordinary gas flame did possess a little. The oxyhydrogen flame, while attended with intense heat, was endowed with very little chemical action. A prepared collodion plate exposed to this light for twenty seconds gave a very faint picture. But when the flame was thrown on lime, although the temperature was lower, the light had sufficient chemical activity to produce a strong picture, on a similarly prepared plate, exposed for the same time. In the case of the chemically acting rays, the intensity, number and position of the lines on the spectrum had been found to vary with the source of light. The most remarkable illustration of this was the different spectra produced by the electric spark of an induction coil between poles of different metals and projected upon a photographic plate.

The spectrum produced by the spark from silver poles, for example, was found to be three times the length of the whole of the solar spectrum transmitted by quartz. In order to obtain views of this invisible spectrum it was necessary to transmit the rays through a medium more transparent to chemical rays than glass, which it had been said, was opaque to the higher rays of this kind, and various experiments had been made to ascertain what substance allowed them to pass most freely. The results were shown in the following table of the—

Photographic Transparency of Solids.

Rock crystal 74	Sulphate of magnesia 62
Ice 74	Borax 62
Fluor spar 74	Bromide of potassium 48
Topaz 65	Thin glass 20
Rock salt 63	Mica 18
Iceland spar 63	Iodide of potassium ... 18
Diamond 62	Nitrate of potash ... 16

The above numbers being founded upon an arbitrary division of the spectrum.

The photographic transparency of liquids differed still more, as would be seen from the following diagram:—

Photographic Transparency of Liquids.

Water 74	Wood spirit 20
Alcohol 63	Acetic acid 16
Chloroform 26	Oil of Turpentine ... 8
Benzole 21	Bisulphide of Carbon 6

Various gases were also found to interfere with the transmissibility of these rays, as exhibited in the table of the—

Photographic Transparency of Gases.

Hydrogen 74	Benzole vapour 35
Nitrogen 74	Hydrochloric acid... .. 55
Oxygen... .. 74	Hydrobromic acid... .. 23
Carbonic acid ... 74	Hydriodic acid 15
Olefiant gas 66	Sulphurous acid 14
Marsh gas 63	Sulphuretted hydrogen 14
Coal gas 37	

The diamond and rock crystal allow the chemical rays to pass freely, but other substances, in which no difference of transparency can be discovered by the eye, considerably affect the transmission of these rays. Chloride of potassium allowed them to pass less freely; and nitrate of potash, and nitrates generally, offered still more obstruction. It was the same with fluids, and also with gases, as would be seen by a reference to the diagrams. It was remarkable, too, that solid bodies when dissolved or melted maintained exactly the same power as when in the solid state. The same was the case when they were converted into vapour, which showed that this power was part of the nature of the substance.

The lecturer then described the phenomenon of fluorescence, and showed that the chemical rays of the spectrum corresponded with the rays of fluorescence by taking a photograph in that part of the spectrum which, though otherwise invisible on the screen, lighted up a solution of resuline. He then showed that all metals give characteristic photographic spectra, some of them bearing a strong family resemblance to each other, as in the cases of iron, cobalt, and nickel, the last metal giving one of the longest spectra observed, and which extended to 190° of the scale. Arsenic, antimony, and tin showed as great differences in the invisible as visible part of the spectrum. The most interesting of the metals to study in this respect was magnesium, which opened a wide field for investigation. There were certain points of resemblance between the spectrum of magnesium and that of the sun, which lead to the supposition that this metal existed in the solar atmospheres. The comparison of the spectrum of magnesium with that of the sun led also to some important considerations as to the temperature of the sun. It was known that the higher the temperature the more refrangible were the rays of light emitted by a body. We have no conception of the temperature of the electric spark. The heat of the strongest wind furnace was estimated at 4,500° F., and that of the oxyhydrogen jet was supposed not to exceed 15,000° F., yet with neither of these could the same effects be produced as with the electric spark. The lines of the photographic spectrum of magnesium were not seen in photographs of the solar spectrum, and yet there was no doubt that this metal was present in the solar atmosphere. Kirchhoff had discovered that solids when heated give a continuous spectrum, but that bodies in the form of gas give rays of definite and limited refrangibility, each substance emitting light of definite property. He had also noticed that light from a luminous mass, by passing through ignited vapour which, *per se*, would give bright lines in the spectrum, became furrowed out in dark bands occupying exactly the same position in the spectrum as the bright lines. Now, ignited magnesium vapour emitted green rays which were absolutely identical with the group of fixed lines *b* in the solar spectrum, and it was therefore certain that magnesium was a constituent of the sun. It was, moreover, probable that the heat of the sun was inferior to that of the electric spark, inasmuch as it was insufficient to bring out the highly refrangible lines observed in photographs of the magnesium spectrum.

There were thirteen bodies known on earth which these researches lead us to suppose existed in the solar atmosphere. Nor are they limited merely to the sun. Fraunhofer had examined the spectra of several stars, and found that although they presented no similarity to that of the sun, nor to each other, yet that some general relationship between them was observable.

Mr. Huggins and the lecturer had recently been investi-

* Read at the Royal Institution, March 6.

gating this subject, and had obtained very perfect maps of the visible spectra of several stars. They had also obtained a photograph of the spectrum (which was exhibited) of Sirius. This star is 130,000,000,000 of miles distant, and the light which produced the photograph must have left it twenty-one years ago.

A photograph of the spectrum of Capella, which is three times further distant than Sirius, had also been obtained, the light to produce which, the lecturer said, must have left that star when the oldest in the room was a little boy. Professor Miller concluded an eloquent address, of which the above is a mere outline, by remarking how much these wonderful facts enlarged our ideas of the power of the great Author of the Universe, whose will "creates, sustains, and animates the whole."

A SHORT LESSON IN PHOTOGRAPHY.—No. 12.*

PRINTS, when removed from the printing frames, cannot be kept long either in the dark or between the leaves of a blank book, before decomposition spoils the surface. This decomposition is attributable to the presence of organic matter in contact with nitrate of silver, and is much more energetic on albumenized than on plain paper. Hence it is necessary as soon as the prints are either sufficiently numerous, or that no more prints are required, to proceed at once to the next steps in the routine of photographic printing.

Take either a pail or a tub, according to the circumstances of the case, depending on the number of prints to be manipulated with. These vessels must invariably be constructed of wood, and never of tin-plate or other metal. Be very particular on all occasions to see that they are perfectly clean from all extraneous matter, and especially from all sulphurizing substances, as sulphide of potassium or decomposed hyposulphite of soda, &c., whose presence would be very deleterious by producing stains that cannot afterwards be removed.

Fill the pail, &c., with rain water, and immerse the prints one by one. This operation has to be performed in the dark-room; keep the prints in agitation for about five minutes; now gather them all together, take them out, and place them for a moment aside in some convenient corner until the water is removed from the pail.

[Some artists, who conduct extensive establishments, first precipitate the nitrate of silver, now present in the water, by throwing into the pail about a teaspoonful, &c., of salt; the precipitate is allowed to subside, and the water is afterwards decanted and thrown away. When such an expedient as this is resorted to, it is better to have a tank into which all the silver washings can be thrown, and in which the chloride of silver can be precipitated as soon as a sufficient quantity of the water has accumulated; the supernatant water is afterwards allowed to flow off; and thus fresh supplies can be introduced, until finally there is formed at the bottom quite a considerable sediment of the chloride. This chloride is then removed, dried, and fused into pure silver.]

Fill the pail again with rain water, and wash the prints as before by continual agitation for the same length of time. Again withdraw the prints and pour the water into the tank; and, finally, with another pail-full of rain water wash the prints once more for about the same length of time. By this proceeding all the superfluous or undecomposed nitrate of silver is washed out from the prints; so that now there remain probably only the superfluous or undecomposed chloride of silver and albuminate of silver to be removed afterwards in the fixing bath. I say undecomposed chloride of silver, by which I mean that portion which, by reason of the dark parts of the negative, has not been acted upon by the light, and which would consequently spoil the prints if allowed to remain.

The parts that form the picture consist of chloride of silver made insoluble by light; this species of chloride, or subchloride, or oxychloride, is not thoroughly understood;

it has received new properties from the light, and might hence be denominated *actinate* of silver, or *actino-chloride* of silver. If any doubt should exist as to the successful completion of the washing of the prints, take one of them, immerse it in a basin-full of rain water, and, after the expiration of a few minutes, remove it from the water, and then add a particle of salt; if a milkiness is thereby produced, the washing has not been complete.

We will suppose, however, it has been complete and proceed. We find it to be an advantage before introducing the prints into the toning bath to pass them through hot water, whereby, probably, the albumen film becomes more effectually coagulated, or the toning by the heat is facilitated, and the time of toning shortened.

The toning bath consists essentially of a solution of chloride of gold made neutral with an alkali or an alkaline earth, as, for instance, with carbonate of soda or with carbonate of lime. Without this addition the gold would not only tone quickly, but bleach the prints quickly. Besides this alkali or earth some artists add an excess of either acetate of soda, phosphate of soda, or citrate of soda. Experience shows that these additions do not produce any very decided advantages if the chloride has been previously properly neutralized.

Again, other artists succeed most satisfactorily with a bath containing an admixture of nitrate of uranium. This bath once formed may be used over and over again, by simply adding from time to time fresh supplies of neutralized chloride of gold and nitrate of uranium.

TONING BATH.

Rain water	1 quart.
Nitrate of uranium neutralized with chalk	3 grains.
Acetate of soda	50 "
Chloride of gold neutralized with chalk	4 "
Chloride of lime	20 "
Alcohol	1 ounce.

By neutralizing the nitrate of uranium or the chloride of gold, by means of chalk, is meant, that to their separate solutions in half an ounce of water pulverized chalk is added until a piece of blue litmus paper first reddened by either solution is just restored to its original blue colour. As soon as this state occurs, the solutions are allowed to settle and poured separately, agitating all the while, into the water with which have already been mixed the other ingredients.

This bath will keep well, and it produces rich purple tones. It works much better, as do all toning baths, when the water is just lukewarm.

Into this bath, after it has been prepared a short time, introduce each print separately, and retain the prints in such a position as to preserve their picture surfaces in direct contact with the fluid, and not in contact with each other. Besides this, keep the prints in motion so as to obviate all abnormal or unequal action. As soon as the tone has become a sort of blue violet, take the prints out, wash them in hot water for a moment, and then immerse them in the fixing bath with the same precautions as in the toning bath, namely, so that their surfaces are not in intimate contact with one another.

FIXING BATH.

Rain water	1 quart
Hyposulphite of soda (to saturation) or about	8 ounces.
Alcohol	1 ounce.

The fixing bath operates much quicker if preserved at a lukewarm temperature. On the introduction of the prints into this bath the tone will change slightly at the beginning, but is afterwards partially restored. Considerable experience is required in the toning, so as to obtain the right shade, which, when fixed, will yield the most agreeable or a given colour *ad libitum*. If a rich sepia brown is required, the prints are not to be toned into the violet, but are to be taken out before they have arrived at this stage. If the hyposulphite of soda is genuine, and the method here prescribed has been strictly adhered to, the time required to restore the tone

* From *Humphrey's Journal*.

and remove all the soluble ingredients will seldom exceed four or five minutes, and is frequently much less than this.

The restoration of tone is in some measure a criterion by which to judge of the fixation; another criterion is the absence of all grey particles in the body of the paper in the transparent parts; if the tone has been thoroughly restored, and the whites are perfectly clean, the prints may be taken out and placed in a pail or tub of clean water, and washed by frequent renewal of the water; they are then allowed to remain in rain water for several hours, until every trace of the hyposulphite has been removed. We will, therefore, leave them in the water until to-morrow.

PHOTOGRAPHY AND BAD TASTE.*

EVERY new art, unfortunately, is sure to bring out a vast amount of bad taste on the part of its ignorant patrons. In these days everything is cheap—at least, most things are capable, so to speak, of being issued in cheap editions; and this tendency is not to be regretted. It is, indeed, one of the best results of civilization that the doors both of knowledge and pleasure are widely thrown open to the masses. The invention of printing first cheapened books; the development of science has cheapened the comforts and even the luxuries of life, so that a humble workman may now live in a manner far superior, in many respects, to the domesticities of a prince three hundred years ago. Art manufactures are making even our cottagers familiar with forms of beauty that will soon displace the monstrosities of former days; and schools of art are preparing the way for a still further extension of the principles of good taste. But it must be owned that the sudden development, in one particular direction, of a taste which as yet is but half informed, has led to much offensive vulgarity, and threatens, if it be not checked, to lower the standard of truthfulness in the popular mind. A large supply of anything, when combined with cheapness, as it is pretty sure to be, generally brings a large demand; and the demand, thus instantaneously and artificially stimulated, is certain to be attended by a considerable amount of ignorance and pretence. People require time to be educated up to the point of knowledge and refined perception. Those who supply them are often equally in want of correct ideas, and at any rate have an interest in producing that which the thousands can most readily appreciate; and thus the new art is for a time degraded. It was so with the invention of printing. For the first century or two after the great discovery of Faust, learned men were led to debate whether or not the printing-press had really proved a benefit to mankind; those who held the negative proposition basing their argument on the assertion that the labours of the compositor and pressman had given greater facilities than before existed for worthless scribblers to inflict their nonsense on the reading public. This evil, however, was one of those which always correct themselves in due time; and so it is with other mistakes of the same character. But in the meanwhile it is as well to see how we stand in regard to the æsthetic and intellectual uses of the most recent inventions.

Photography is an art peculiarly liable to be perverted to base uses. It is cheap (that is to say, when badly executed), and therefore appeals to a large class of uneducated people; it is singularly well adapted to minister to personal vanity, and to keep pace with the incidents of the day; and it is capable of producing, especially when combined with the stereoscope, effects which are more startling than artistic in their nature. All these facts form a perpetual incentive to the photographic manufacturers to lower what might otherwise be esteemed one of the fine arts, to the level of clap-trap, and sometimes to far worse uses. The Society for the Suppression of Vice can tell us something of one of the purposes to which photography is applied, and we know not

how many cartloads of immoral slides have been taken away from the sombre dens of Holywell-street and Wych-street. The police make a seizure of this kind every now and then; but there can be no doubt that the trade still flourishes, because a demand exists for these wretched incentives to evil. Then there are the photographs which may be seen even in respectable shop windows, and which just daily with questionable situations—just faintly suggest ideas of impropriety. Let us hope, however, that both these classes of photographic pictures appeal to a comparatively limited class of buyers. The majority of bad photographs are reprehensible on the ground of taste rather than of morality. Considered in this way, the detestable portraits, executed "in this style" for sixpence or a shilling, are really a nuisance, though the annoyance is one which cannot be abated by any other means than instilling into the mind of the community better notions of art. Nothing can be more natural or commendable than that John Brown should wish to possess a "correct likeness" of himself, to be presented to Mrs. Brown, or Jemima Higgins, his intended bride, or, perhaps, to his mother. But it is surely not a good thing that plain John Brown should be induced by the "artist" to assume the aspect and bearing of a brigand in broadcloth; or of a poet, Byronic and sentimental; or of a statesman, revolving in his anxious brain the fate of empires and of ministries, the consolidation of our power, and the liquidation of our National Debt. Nor is it at all desirable that when Jemima Higgins, in her turn, honours the "artist" with a sitting, she should be forced to take upon herself a Siddonian mien, as though just uttering the words, "Give me the daggers!" We say nothing of the cruelty inflicted on the general public by the wholesale exhibition of these monstrosities (framed and glazed) at the outer doors of the "studio;" or the annoyance of being pursued, for half a dozen yards along the pavement, by a loud-voiced, ruffianly-looking fellow, who bullying invites you to come in and be "done," and who, but for the fear of the police, would probably fight for the possession of your person, carry you into his den by main force, and "do" you in such a way as he might consider best suited to your particular style of physiognomy. These are matters of social arrangement, which, according to our English custom, must be left to settle themselves. But we must, on artistic grounds, protest against cheap photographic likenesses. It may be said that, if they satisfy their purchasers, and enable poor and humble people to gratify a vanity always harmless, and sometimes associated with affectionate thoughts of others, they do all which they pretend to do, and even answer a good end. This is very true as far as it goes; but if, by educating the perceptions of the lower orders to a better knowledge of what is truthful and reasonable, the more cultivated classes can save them from such nightmare phantasms of bad taste, it would surely be a desirable result. Vulgarity is not a necessary element of cheapness; it is only a necessary result of ignorance. The history of the last five-and-thirty years has shown what excellent literature may be published at a trifling price; and when good art is equally appreciated with good writing, art producers will find themselves obliged to seek for popular custom by a higher style of conception and execution than they at present display in the cheapest class of their works.

But it is not merely in the humblest stratum of society that bad taste in photography finds a ready market. It flourishes abundantly in the middle class. Every street passenger must have noted those portraits of royal personages with which the shop windows have recently abounded. Probably he has got a round dozen or so of them in his album. He is a loyal man, and wishes to have about him what he considers authentic likenesses of the sovereign, of the Prince and Princess of Wales, and of the other members of the family that reigns over us. Even if he does not care about such matters, his wife and daughters do, and the photographs must be had. Besides, they cost only a shilling each, so that for a guinea or two we might almost provide ourselves with illustrations of the whole *Almanac de*

* From the *London Review*.

Gotha. The photographic artists of Belgium know where their most numerous customers are to be found; and Brussels supplies England with the means of gratifying her curiosity in this respect. Paterfamilias buys a heap of shilling *cartes de visite*, and fancies that he has got the veritable effigies of royalty. He does not know that a vast number of these supposed portraits from the life are "cooked up" by foreign artists, whose main object is to make everything look pretty and sentimental. The result is often miserably false and bad. Here, for instance, we have lying before us a card which contains portraits of the Prince of Wales and the Princess Alexandra, issued several weeks before they were married. His Royal Highness sits in a chair, while the Princess stands over the back of the chair, with her two hands resting on his two shoulders. Pretty, is it not?—sentimental, sweet, and lover-like? Very—only not quite probable, or in the best taste. That a young lady may have stood, in that attitude of tender watching, at the chair of her future husband, is likely enough,—but she would never think of being photographed at so confiding a moment. The lover would certainly object to the artist "posing" his intended in any such way, and the lady herself would object to it with still greater vehemence. Can Paterfamilias possibly believe that the Prince and Princess allowed themselves to be shown after this fashion to the general gaze? Yet we believe that this particular *carte* has sold enormously, together with its companion, in which the position of the figures is reversed. Then there is another photograph, representing our widowed Queen contemplating a portrait of the Prince Consort, with the royal children grouped, in the manner of a tableau, around her; and there is another, still more theatrical, depicting the Queen and the young Princesses wreathing a bust of the departed with festoons of flowers. Within the last few days we have even been introduced in this way to the very death-bed of Prince Albert! The publisher thinks the photograph will be an "attractive, though sad" memorial; and he is probably well assured of his ground.

It is quite lamentable that any one should believe these fancy pictures to be photographs from life, or real scenes: yet we doubt not that they are generally so accepted.* People are actually so ignorant as to suppose that her Majesty, who has withdrawn herself from public life ever since her great affliction, would have permitted a photographer, for his trading purposes, thus to invade the very privacy of her grief.

The manufacture of these photographic impostures says little for the honesty of those who produce them; and it also suggests the existence of a great deal of bad taste in the English public, or these articles would not obtain here so large a sale as they do. But for the existence of that bad taste, the untruthfulness of such sketches would at once be detected. They are thought, especially by women, "pretty" and "interesting;" and the gross improbability of their composition goes for nothing. They are not beautiful as works of art; they are not truthful in any sense; but, like Packwood's razors, they are made to sell, and they *do* sell.

* There is, we regret to say, too much ground for the charges of bad taste imputed in this article, which, as a whole, is worthy of the serious consideration of photographers. The writer is, however, woefully misinformed with regard to facts. In reference, for instance, to the group of Her Majesty contemplating a portrait of the late Prince, and also his bust wreathed with flowers, the writer intimates his conviction that it is a spurious photographic manufacture; he is manifestly not aware of the fact, that, the photographer by whom it is issued possesses at least a quasi-official connection with the royal household, and sends this picture forth by the express permission of Her Majesty. We do not presume here to offer any expression of opinion on the question of taste, beyond remarking that the want of better information or of a more discriminating judgment, has caused this writer to be guilty of the bad taste evinced in criticizing the decisions of a royal lady on a subject which did not in any way necessarily challenge his attention. Taste is a question on which there may be differences of opinion; but there can be no doubt that the motive which induced Her Majesty to thus admit her people, to share, as it were, the privacy or domesticity of her grief, is one which should meet with tender sympathy. The writer is also manifestly in error in his allusions to M. Ghemar's pictures, of the genuineness of which there cannot be a doubt, that artist having been honoured with sittings, not only from the Prince of Wales and his intended bride, but by the Queen and several other members of the Royal family.—ED. PHOTO. NEWS.

The Belgian artists know our weakness and find their own strength in it. A people possessing a widely diffused perception of what is artistic, would not be bamboozled by such false pretences; the power of apprehending the highest forms of art being one with an instinctive sense of verisimilitude. The strange part of the business is that we English, despite our dullness in matters of art, should not perceive, by the mere strength of our honest love of matter of fact, the absurdity that is palmed off on us. But when the matter of fact man takes to art in any form, he is generally best pleased with that which is false. The artistic world being an utterly strange world to him, he makes the mistake of supposing that untruthfulness is the law of its existence. He demands "effect" above all things, something that will give him a sensation beyond his ordinary round of ideas; and whatever does this commands his enthusiasm and his patronage.

PHOTOGRAPHIC PIRACY OF ENGRAVINGS.

SHERIFFS' COURT, *Red Lion Square, April 2.*

(*Before Mr. Under-Sheriff BURCHELL and a Jury.*)

GAMBART v. SCLATER.

THIS was an action brought in the Court of Common Pleas under the 17th George III., chap. 57, and the 8th George IV., chap. 113, for an infringement of the copyright of the engraving "The Light of the World." The damages were laid at £500, and the defendant, who resided at Canterbury, having allowed judgment to go by default, a writ of inquiry was executed to assess the amount to be awarded.

Mr. Biron appeared as counsel for the plaintiff; the defendant was not represented.

In opening the case to the jury, the learned counsel stated that the plaintiff, Mr. Earnest Gambart, was the well-known printseller in Pall Mall, and was a great promoter of art. He had published engravings of Rosa Bonheur's "Horse Fair," Frith's "Dorby Day," and Holman Hunt's "Finding the Saviour in the Temple," and "The Light of the World," by the same painter. It was in respect of the last picture that the present action was brought. Mr. Gambart had expended large sums on the works, and they had been photographed, and sold at very small sums—from 1s. to 10s.—when the price charged was from two guineas to ten guineas. Mr. Gambart had sustained a very serious loss and could not account for the decrease in the sale of the "Light of the World," which had been one of his most successful productions, until he discovered that it had been copied and sold by such persons as the defendant in country places. The defendant was a shop-keeper at Canterbury, and boasted, when called upon, that he had sold a considerable number. The only remedy for Mr. Gambart was to bring the present action, and unless the jury gave substantial damages the great works of art would be pirated, and publishers, unless protected, would not embark in any enterprize on the subject, and the public would be the losers.

A traveller named Lefevro proved the purchase of a photographed copy of "The Horse Fair" and "The Light of the World," at the defendant's shop at Canterbury, for a few shillings; and he told him he had sold a great many of them.

Mr. Gambart stated that he had given Mr. Holman Hunt 200 guineas for the privilege of engraving the picture of "The Light of the World." He had paid the engraver over 300 guineas as his fee, and £130 to the owner of the picture for allowing the engraving to be made. With other expenses, including canvassing and advertisements, he had expended upwards of £2,000 in bringing out the print. The print had been published about three years ago, but he had been five years about it. The print was his most successful production, and he realized the first year about £10,000. He discovered that about two years ago there was a great falling off, which was not to be expected from the success it had achieved, and he ascertained that, with others of his productions, it had been photographed, and sold for a few shillings. He had sustained a considerable loss. His prices were from one to eight guineas. The manner in which photography had been used to copy his productions was a serious injury to him; and on one occasion, when he consulted Sir Richard Bethell (the Lord Chancellor) on the subject he preferred the photographed copy.

Mr. Under-Sheriff Burchell remarked that some one must get the advantage. He supposed it was the public.

Mr. Gambart said he was greatly injured. Photographers could produce copies for 1½d.

The learned Under-Sheriff had no doubt there was "great light in the world," but whether it was the "light of the world" was another and a very different question.

Mr. Graves, printseller, of Pall Mall, was called to prove the loss Mr. Gambart was likely to sustain by having his prints copied.

Mr. Under-Sheriff Burchell could not see how the question could be asked. The defendant, he was sorry, was not represented, and he could not see how it could be proved against him what injury Mr. Gambart had or was likely to sustain. The question was, what damages Mr. Gambart could recover against the defendant, and not the injury likely to accrue to Mr. Gambart by photographing his production.

Mr. Graves said that unless printsellers were protected it would lead to the destruction of the trade, as no one would give a large price for permission to engrave a picture.

A resident at Canterbury, named Ginger, who had acted as agent for the sale of the print, stated that he had obtained subscribers to the amount of 70 guineas, and after the defendant sold copies by photography the sale fell off. He called on the defendant, and he abused him. He was now selling the copies.

Mr. Under-Sheriff Burchell thought the jury should know what occupation the defendant followed, as it would assist them in estimating the damages to be awarded.

It was proved that he was a shopkeeper and a maker of picture-frames.

The learned Under-Sheriff, in placing the case before the jury, told them that the only question for their consideration was the amount of damages to be awarded for the infringement of the copyright, as, by allowing judgment to go by default, defendant had admitted that the plaintiff had a right of action against him. The question was, no doubt, a difficult one, and the defendant had not thought proper to appear and offer any explanation as to the course of conduct he had pursued. The plaintiff had stated the sum he had paid for the work of art in question, and also that the sale had fallen off in consequence of the photographed copies being sold. He had not allowed him to be asked what loss he was likely to sustain from such conduct, because it could not be fairly submitted against the defendant. He had not sat in that Court so many years without knowing that a man could not be permitted to estimate the damage he was likely to sustain. He would further say that the jury were not there to punish the defendant, but merely to compensate the plaintiff, so far as he was concerned, for the injury of which he complained, as against the particular individual.

The jury consulted in the box and wished to retire. After a short consultation they returned into Court with an assessment of 100*l.* damages.—*Times.*

Proceedings of Societies.

LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of the London Photographic Society was held in King's College, on the evening of Tuesday, April 7th, Mr. P. LE NEVE FOSTER, M.A., in the chair.

The minutes of a previous meeting having been read and confirmed,

THE CHAIRMAN called attention to some views of India which he thought were superior to anything he had seen done in that country. They were produced by Mr. Elphinstone Underwood, the President of the Madras Photographic Society, a gentleman whose name would be submitted to the meeting for election as an honorary member of the body.

A revolving pillar stereoscope, with some five transparencies of Japan, &c. was exhibited by Messrs. Negretti and Zambra.

The following gentlemen were elected members of the Society:—Messrs. J. R. Johnson, W. Elphinstone Underwood, and Thomas Brooks.

It was announced that the two promised papers, one by Mr. Heath and the other by Mr. Johnson, would not be read; these gentlemen being unable to be ready in time.

Mr. SHADBOLT produced three specimens of panoramic pic-

tures taken on a flat plate with a common lens. He said that the fact that they had been produced some time ago did not detract from the merit of Mr. Johnson's invention, as no account of those he now produced had been published; they were merely placed in his hands as a record of the fact that such a thing had been done. The first picture to which he would call attention was the interior of a room, and if anything would show forcibly the fallacy of circular, or panoramic photographs, this would, as it gave the four sides of a room, and a little over, on one flat plane. Another picture was a landscape view, and in it a straight road was sadly distorted. Apart from these specimens, he held in his hands the specification of a patent dated October 6th, 1857, which seemed to him to embrace, not only all that had been done, but all that could be done in that direction. The patent was obtained by Mr. Brooman, and the invention was stated to be a communication from M. Garella.

THE CHAIRMAN referred to Marten's panoramic camera for daguerreotype plates.

Mr. SHADBOLT remarked that M. Marten's camera was for producing panoramic pictures on a curved surface, but this patent was like Mr. Johnson's, for producing them on a plane surface. So far as a patent was concerned for the latter gentleman's invention, it was out of the question altogether. The principle of M. Garella's was for a motion of the plate in proper ratio to another motion of the lens and camera, and he presumed Mr. Johnson's was of a similar character, but probably simplified and improved.

THE SECRETARY read a communication from M. Rolloy of Paris, recommending his varnish, which was stated to consist chiefly of white lac in alcohol, prepared in some peculiar manner.

Mr. JOHNSON wished to say a few words in reply to Mr. Shadbolt. He was perfectly aware of the various attempts which had previously been made to produce panoramic pictures on flat plates. M. Garella had attempted it; Mr. Sutton had attempted it before he invented his lens for curved plates; and others had attempted. But what others had attempted and failed in achieving, he had succeeded in doing. He did not claim any novelty in principle; all he claimed was the difference between success and failure. The specimens Mr. Shadbolt had brought that evening were striking illustrations of the former failures, and were very unsuccessful indeed, showing that the motion applied was altogether inadequate to produce the end. Regarding the alleged distortion, the result was, of course, in what was termed panoramic projection, in which parallels vanish in curves; but if the eye, in examining the picture, were placed at the proper point of sight, all appeared right.

Mr. DEBENHAM wished to say a few words in answer to a communication from Mr. Penny, which had appeared in the PHOTOGRAPHIC NEWS. He had hoped that Mr. Simpson would have brought forward the specimens that evening, together with some promised results of his own, but he understood from that gentleman that he was suffering from some indisposition, and would not therefore bring the matter forward.

Mr. WHARTON SIMPSON said if Mr. Debenham would allow him he would willingly place the specimens before the meeting, but he was not then prepared to enter into any comment, beyond pointing out that from the specimens of Mr. Penny in his hands an undoubted accession of sensitiveness appeared to have been obtained.

Mr. DEBENHAM resumed: he thought he could easily explain the discrepancy of experience. Mr. Penny's bath was stated to be acid with nitric acid, and therefore not in the best condition for sensitive results. With a bath in such a state, it was possible that fuming might to some extent have connected it, and hence the improved results described. He should not enter into any comment upon what he conceived to be the unnecessarily personal remarks upon himself.

Dr. WRIGHT, recurring to the communication of M. Rolloy, thought that although it partook more of the character of an advertisement than anything else, it might have originated an interesting discussion upon an important subject. He referred to one or two singular and annoying circumstances connected with varnish occurring in his own experience, one of which was a portion of the image being dissolved off by Schönée varnish. He attributed this to the plate being too dry before immersion in the bath, and so causing the image to be entirely superficial, instead of in the film. He also mentioned the value of a glass coated with spirit varnish chilled, as a substitute for a broken ground glass.

Mr. J. W. OSBORNE said, that he had used amber varnish in hot climates, and although the plates had been exposed to a temperature of 130°, he had never known the varnish stick to the paper, as alleged by M. Rolloy. In his own particular work he used a solution of gum arabic applied before drying the plate, which answered every purpose so long as the plate was kept dry. This he managed by using tin-plate boxes instead of those made of wood. He thought the tin boxes had many advantages which made them superior to wood; they gave more space for storage, and preserved the plates much better from damp.

Dr. DIAMOND said other causes would sometimes make the varnish dissolve off the image, besides the plate being too dry before going into the bath. It had recently occurred in his hands, from the use of a horny collodion, which kept the image on the surface instead of permitting it to permeate the film properly. With another sample of collodion, treated in all respects in the same way, the image did not dissolve.

Mr. SHADBOLT had not heard any suggestion from previous speakers as to the real cause of the varnish dissolving the image. It was well known that some samples of pyroxyline were to some extent soluble in alcohol, and as the Sehnée varnish was made with strong spirit it would dissolve a film constituted of such cotton; but the dissolving had nothing whatever to do with the image being merely on the surface.

Dr. DIAMOND said that in the case to which he referred the film was not dissolved, but was there clean and horny after the image was dissolved off the surface. A sample of the collodion was at Mr. Shadbolt's service if he wished to convince himself.

Dr. WRIGHT said in his negatives the film was not dissolved, but remained quite perfect, the image only was removed by the varnish.

Mr. ELPHINSTONE UNDERWOOD referred to the difficulties of obtaining good varnish suitable for India, and also to the difficulty of obtaining anything but hard negatives there.

After some further conversation it was announced that a number of the prints of the late Prince Consort were ready and would be distributed by ballot. It was also announced that at the next meeting Mr. Richards would exhibit some apparatus by M. Bertsch, and that papers by Mr. Johnson and by Mr. England would be read. Also that at the June meeting Mr. Brookes would read a paper "On the Latent Properties of the Blue Ray in regard to Iodide and Chloride of Silver."

The meeting then adjourned.

THE AMERICAN PHOTOGRAPHICAL SOCIETY.*

The Society held its regular meeting for March, on Monday 10th inst., at the University. President JOHN W. DRAPER in the chair.

Collodion Films.

Mr. F. F. THOMPSON exhibited some collodion films of negatives taken in the Imperial print works at Vienna. The films were detached from the glass, and sent to the president of the Photographic Society of Philadelphia, who had sent them here for exhibition, as an interchange of friendship between the two societies. By daylight the film is very yellow and dull; it prints about twice as slow as a glass negative. The gelatine which is used with the collodion seems to destroy the brilliancy almost entirely.

Professor SEELY said that in galleries where they sometimes have a ton of negatives, a practicable process of removing the film would be very useful. Gutta-percha had been suggested for this purpose. There is no difficulty in removing the film with gelatine, and probably would be none with a gutta-percha solution in benzole or chloroform. Moisture would probably have an injurious effect upon gelatino, which would be an objection to its use for this purpose.

Col. PIKE stated that he had frequently removed collodion films by pouring over the plate a weak solution of cyanide of potassium, which starts the film immediately.

Mr. THOMPSON remarked that these films were very convenient for packing; but considered this no compensation for the want of brilliancy in the prints.

Professor SEELY called attention to the fact that these films are so sensitive to moisture that the moisture of the hand or of the breath makes them move, curling like the leaves of the "Chinese love-plant."

The PRESIDENT remarked that dry shavings, or horn, or gelatine, are affected in the same manner.

Cameras for Travelling.

Mr. THOMPSON exhibited and explained a camera box, containing all the apparatus, excepting the tripod, and a dozen prepared plates eight by ten inches, the whole weighing no more than a pail of water. He exhibited also a sample of the work from a plate which had been prepared more than two years before the picture was taken upon it. He said that the box he had exhibited and which was invented by Mr. Hughes, of England, weighed but half as much as Mr. Stock's box. He had carried it twenty-five miles in a day; and he had never had any trouble with it in practical operation. This picture was taken from one of Norris's prepared plates, sent to this country two years ago, having then been prepared several months. These were gelatine plates; but tannin plates, well packed, will keep equally well.

Col. PIKE said that to prepare plates for keeping, two grains of gallic acid should be put into fifteen grains of tannin; and the plates should be washed well, and the solution flowed over them; and then they would keep any number of years, if kept in a dry place. The tannin should never be used a second time. There seems to be some chemical change in it, unfitting it for repeated use. He objected to the plan of washing plates under a tap. It was better to immerse them in a dish of clean water, moving it about gently.

Mr. MASON: Does the acid make any difference in the sensitiveness of the plate?

Col. PIKE: Not at all.

The Effect of Washing Plates.

The PRESIDENT called up the subject selected for this evening, being "The Effect of Washing Plates," and said the operation referred to, in selecting this subject, was this:—In the wet process, after having immersed the plate in the nitrate bath, it is thoroughly washed to remove the nitrate of silver it contains; it is then exposed in the camera; and in the subsequent development it must receive a sufficient quantity of nitrate of silver to replace that which has been washed away. The advantages which seem to follow from this manipulation are the extreme purity and cleanliness of the result. In the washed plates, we never see holes, specks, black dots, or anything of that kind. The surface is perfectly pure and clear. Nor do we ever see those white silvery stains that come up chiefly from the lower part of the shield. Upon such a plate, developed and dried, the collodion film is perfectly glassy, looking as transparent as the glass itself. Another advantage is that the state of the bath, as regards its said condition, becomes comparatively unimportant. An acid bath seems to work nearly as well as one perfectly neutral. The drawback upon the operation is that it diminishes the sensitiveness of the plate. But where great speed is not essential, he regarded the process as a considerable improvement.

Col. PIKE stated that, two years ago, having occasion to work the wet process, he found upon developing his pictures that they had streaks across the plate. After various experiments, for three months, he had determined to wash the plates thoroughly; he then obtained good pictures. And to this day, he continued the practice of washing the plates; although in gallery work it diminishes their sensitiveness so much as to be impracticable. In developing these washed plates, by using a few drops of pyrogallic acid, he could get any required intensity.

The PRESIDENT said that his son, Dr. Henry Draper, who had occupied himself a good deal in astronomical photography, had found that the washing operation very much facilitated his operations. He could prepare quite a number of plates in the beginning of an evening, and could keep them in saucers of water for several hours, if required. In taking lunar photographs, for instance, clouds are apt to interfere; but the plate is all ready for use at any moment. The diminution of the sensitiveness of the plates may not be so great as some imagine. From the accounts given by Mr. De la Rue and other foreign gentlemen who have taken lunar photographs, making due allowances for the optical effects of the instruments used, it appears that a washed plate will give a representation of the surface of the moon very nearly as quickly as those not washed.

Dr. HENRY DRAPER remarked that the difference seemed to a great extent to be that the washed plates require much more time for their development. The picture will not flash out, as from a plate not washed. But a developer can be placed upon

* Abridged from the *American Journal of Photography*.

the plate for twenty minutes or more, and the picture growing better all the while; the clear parts remaining perfectly clear without any fogging. And although the density of the black portions may not be so great, yet the absolute purity of the light portions may cause the picture to be quite as intense as from the other process.

Mr. BURGESS asked for a more detailed description of the process.

Dr. HENRY DRAPER: I use for celestial photography any good collodion immersed in a forty grain (acid or neutral) bath. The plate, being washed, is exposed. On removal from the camera, it is again put under the tap. Then a pyrogallic and nitrate of silver solution is poured on. It is composed of two drops each of the following, in two drachms of water:—1st. Pyrogallic acid, 72 grains; alcohol, 1 ounce; 2nd. Nitrate of silver, 20 grains; citric acid, 50 grains; water, 1 ounce. The development is quite slow, occupying sometimes twenty minutes. Doubtless too the exposure is longer. But there is no comparison between the results obtained in this way and those by the usual wet method. The former are much purer and clearer in the transparent parts, and there is no trace of fogging. They will bear much more subsequent magnifying.

The PRESIDENT: When these pictures are properly developed, they are so black that you can barely see the sun through the darkest, densest parts. With proper development, you will have as dark a picture as you can get with any photographic process.

Mr. BURGESS suggested that this process would be valuable in copying engravings, or in copying photographs.

Col. PIKE said that Professor Seely had suggested to him some months ago to try an experiment of using the ammonia nitrate of silver for pictures exposed the fractional part of a second. He had tried the experiment and sometimes with such success that he would recommend others taking instantaneous pictures to try it. It would be excellent in the galleries, for taking children.

Professor SEELY said that the process of washing the plates had a great deal of novelty in it; but it reminded him of some experiments he had made three years ago. He had then been troubled with a sandy or mottled surface upon negatives. We now know that this arises from impurities in the nitrate bath. In order to demonstrate this, he had proposed to dip the plate in the bath, and after sensitising it, to wash it off and expose it in the camera. There were two trials, the exposure being about one-third longer, and the result was a very clean picture, without any signs of mottling. The development also, as he expected, was slower. The experiment of washing the plates was tried for that purpose only, and there it rested. These suggestions now came with a great deal of novelty, and something useful may come from them. The difficulties as to the development may be easily overcome. Another advantage in this process is the saving of silver which may be effected by it.

The PRESIDENT remarked that even when the exposure had been too short, even the most delicate parts of the picture are all perfectly there; it is only a tax upon patience in the development to bring them out. But we may have a dozen plates developing at once if we please.

Professor SEELY: Has a trial been made of insufficiently washing the plates, so as to leave a small quantity of silver upon them?

Dr. HENRY DRAPER: No sir; the silver was always washed off as clean as we could. The difficulties that exist in photographing with a Newtonian reflector, bringing the plate nearer the open window, instead of the ordinary refracting telescope, where the plate is at the end farthest from the window, made it necessary that we should wash the plate as completely as we could.

Professor SEELY suggested pouring over the film, after washing, a solution of ten grains of nitrate of silver, which would perhaps unite the advantages of washing with the advantage of sensitiveness.

Camphor Crystals.

Mr. TILLMAN referred to a paper on the subject of camphor crystals, and experiments which the President (Dr. Draper) had made with them.

The PRESIDENT: These camphor experiments always present themselves pleasantly to me as being the first thing that drew my attention towards photography and the action of light upon various substances. I think it was in 1828, while attending

lectures as a student in the University of London, a large glass globe containing camphor was introduced, and upon the sides towards the window there were large and magnificent crystals; and the observation was made that the crystallization was due to the influence of the light, but that up to that time nothing was known respecting the manner in which it took place. That excited my curiosity a good deal, and I tried the experiment for myself. I soon found that the operation would be vastly improved by exhausting the air from the vessel previous to the exposure. Instead of taking several days, the crystallization would take place in an hour. After a great many experiments, I ascertained that a piece of tin foil upon the glass would protect the glass from crystals behind the foil and for half an inch from it. I finally came to the conclusion that the old theory was incorrect; that the crystallization was not caused by the light, but by the heat. The side of the vessel nearest the sky becomes the coldest, and the camphor crystallizes upon it simply by virtue of its being a cold surface. Anything placed before it to obstruct radiation, will prevent the formation of the crystals. That was the explanation I gave of that fact and others connected with it more than twenty years ago. The same explanation has been given within a few weeks, which led to a reclamation upon my part.

The Actinic Spectrum.

Professor JOY translated an extract from the supplement to No. 232 of the *Allgemeine Zeitung*, with reference to experiments by Steinheil and Albert, in which they state that the yellow, green, and blue portions of the spectrum cannot be photographed.

The PRESIDENT said that their experiments must have been very badly made, for he had taken photographs of the solar spectrum from the extreme red to the extreme violet, and extending as much farther beyond the visible spectrum. He had sent such a photograph to Sir John Herschel, in 1842, a long account of which was published in the *Philosophical Magazine* in 1843 with a steel engraving. There were probably as many new lines in that spectrum as in all of the spectrum that had been examined before.

Professor JOY remarked that he read the extract to give the president an opportunity to reclaim that discovery also. Mr. Rutherford had also photographed the whole spectrum.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, April 8th, 1863.

At the last meeting of our Photographic Society, M. Ch. Vinois suggested a mode of taking a good view of a building or other object when, from the contracted space around it, it is difficult to find a place for the camera and obtain a good picture. This inconvenience he proposes to remedy by placing a mirror before the object to be photographed, and then pointing the camera to the reflection of the object in it instead of to the object itself. By this means double the ordinary field of observation is obtained; it is true the image is reversed, but that defect can be easily remedied. He claims that this method presents many advantages in taking portraits. The mirror is supported on a painter's easel.

M. Bertsch objected that every mirror reflects two images of an object; one from the surface of the glass, the other from the surface of the mercury with which it is silvered; and that, moreover, the two surfaces of a plate of glass were rarely parallel, so that the two images reflected would scarcely coincide. To this, M. L'Abbé Moigno and M. Lemaitre replied that they had seen mirrors placed opposite a model to augment the distance.

M. Bertsch admitted that the thing was possible by arranging the mirror at 45° from the model in an atelier, for example, in taking portraits; but in proceeding to take views of public buildings no mirror could increase the angle embraced by the objective, consequently, we cannot accomplish the aim proposed by M. Vinois.

M. Couvreur addressed a communication on the danger presented, in certain modes of treating deteriorated silver baths, he says: "I am accustomed, when my positive silver bath is blackened by organic matters, instead of treating it with a chloride or a phosphate which, it is true, clarify it, but which at the same time weaken it—to evaporate it to dryness; and adding nitric acid, afterwards fuse it. The nitric acid and nitrate of silver entirely destroy the organic matters, and a little silver is found reduced. As in chloridizing my paper I exclusively employ chloride of ammonium, the nitrate of ammonia produced is volatilized, leaving me a nitrate of silver only very slightly coloured grey by the reduced silver.

"Next adding some drops of nitric acid, and evaporating it anew to dryness, and also gently fusing it, a very white nitrate of silver remains, which gives me a pure nitrate of silver bath without any loss of silver.

"I do not pretend that the process I employ is a new one, and only because I think many persons may employ it that I think it useful to caution those who are unaccustomed to chemical reactions of the danger they incur in adopting this method, as well as that indicated by M. L'Abbé Laborde, who advises the addition to the nitrate bath of a given quantity of alcohol, with the view of rendering the impregnation of the paper more rapid and complete.

"I have tried this addition, and find that it gives good results. But after making use of this bath, I afterwards evaporated it, and added the nitric acid as advised above: my bath was rather strong, containing 20 per cent. of nitrate of silver; when the liquid was warmed, I obtained, as may be easily proved, some fulminate of silver."

We can, certainly, avoid this objectionable result by previously diluting the bath with as much water as will reduce its strength to 8 or 10 per cent. of nitrate of silver at the most, and taking care not to add the nitric acid until all odour of alcohol has disappeared.

M. Kessler has invented a new apparatus for evaporation and distillation, to which he gives the name of *erorateur*. It is adapted for chemical purposes, and will be found useful to photographers, either for distilling water or for evaporation. M. Davanne, who presented the apparatus to the Photographic Society, stated that he had, during several days, employed it in the distillation of water, alcohol, ether, in the treatment of old collodion, and in the evaporation of the mother waters of the double sulphate of iron and ammonia, and in all cases had obtained satisfactory results.

For distilling water, by heating rapidly, and abundantly cooling the upper plate, he was able, with the small copper apparatus, to obtain as much as three litres ($5\frac{1}{2}$ pints) of water per hour, which, if not absolutely pure, was equal to that furnished by an ordinary alembic. If the water is required in an absolutely pure state, we must collect only the water of emanation, that is to say, evaporated without ebullition. In making use of the three plates the distillation of alcohol proceeds rapidly, without its being necessary to lute the edges. If it be desired to distil ether, the evaporation is just as simple, only the precaution must be taken to cover the joints with a strip of glued paper.

The double *erorateur* serves also for distilling old collodions; the lower basin serves as a *bain-marie*; the liquids to be distilled are placed in the middle one, and a continuous current of cold water cools the upper plate. By a well managed distillation we can easily separate, first the ether, and then the alcohol; the gun cotton and the iodides remain in the basin. We must, however, before making the distillation, deprive the collodions of their colour by the addition of a very small quantity of caustic potassa, to prevent the volatilization of the iodine, which would colour the distilled products. This operation is preferably made in a porcelain *erorateur*, for the residue of the collodions destroy the tinning of the copper apparatus.

The porcelain apparatus must also be employed whenever we desire to concentrate solutions of photographic salts in order to obtain crystals.

The various experiments made with the *erorateur* lead M. Davanne to conclude that this apparatus, on account of its small bulk, may prove very serviceable to travelling photographers: it is equally useful to photographers who desire to purify their chemicals.

M. E. Renet proposes to substitute tartaric acid for formic acid, in the developing bath of sulphate of iron; his formula is—

Sulphate of iron ... 6 parts, by volume, of a solution at 9 per cent.
Tartaric acid ... 4 parts, by volume, of a solution at 4 per cent.

These proportions are not arbitrary, the author, for want of leisure, has not yet determined the best proportion. His sole object is to call the attention of photographers to the good results obtained by the addition of tartaric acid to sulphate of iron.

The mixture of the two solutions gives a compound of the colour of olive oil.

The conditions under which M. Renet operated are as follows: his collodion is a mixture of numerous old collodions of different formulae, containing various bromides and iodides; a special collodion is not indispensable. The plate is sensitized in a bath of 7 per cent. nitrate, immersed in it 20 or 30 seconds. Exposed and developed in the solution of iron and tartaric acid. This developer does not act upon the latent image immediately. It begins to appear after three or four seconds, and gradually acquires the desired intensity if the exposure has been sufficient, and without the necessity for intensifying. The half-tones have a delicacy which neither sulphate of iron nor pyrogallie acid employed alone can give. The general tint of the negative, after fixing, is an intense blue black.

THE GLOBE AND TRIPLE LENS.

DEAR SIR,—In your report of the proceedings of the North London Photographic Association, of Wednesday, March 18th, 1863, you state that Mr. Harrison's globe lens possesses an advantage over my new actinic triplet.

Allow me to inform you that Mr. Dawson (Professor of Photography at King's College) and myself made several comparative experiments with the two lenses in question, and the conclusion arrived at was, that my actinic triplet possessed this decided advantage over the globe lens, that its definition was incomparably superior.

Doubtless, sir, you have seen the globe lens, and, from your intimate knowledge of the effects produced by the various forms of lenses, you will see that the globe lens possesses positive spherical aberration in a very marked degree, so much so, indeed, as to render necessary the use of a remarkably small stop in order that this aberration may be reduced to a minimum.

I may state that Mr. Dawson has, at King's College, several negatives which fully confirm the fact that my actinic triplet produces the most brilliant and best defined results.

Permit me to say, in conclusion, I hope you will not regard this as an attack on the globe lens, my only object being the rectification of an erroneous statement in which I feel personally interested—I remain, dear sir, yours truly,

THOMAS ROSS.

March 30, 1863.

[On a reference to the report in question, it will be seen that we expressed no personal opinion of the globe lens, but simply recorded Mr. Dawson's remarks thereon. The alleged advantage was not an advantage *per se*, but one merely due to its longer focus. We have already, in these pages, stated that the globe lens possesses considerable spherical aberration, and does not give even tolerable definition without a small stop. It is not, in our opinion, comparable in general qualities to the triple.—ED.]

To Correspondents.

YELLOW GLASS.—Two samples of glass from "S. W. B.," and from "J. M.," have been forwarded, with a request that we will report as to their photographic value. The sample from "S. W. B." is of a dark orange body coloured glass, and, to a casual observer, would appear quite dark enough for glazing a dark room with. The spectroscopic, however, reveals that some chemically-acting rays of light struggle through, although in very small quantity. The specimen from "J. M." is flashed glass, rather darker than the former sample, and quite opaque to the chemical rays of light.

P. M.—Cyanide of potassium will readily remove a fresh silver stain; but if it be old, or, indeed, in all cases, it is well to convert the silver first into an iodide, as it is then more soluble, and more easily removed. The following mixture is useful to keep on hand:—

Spirits of wine	1 ounce
Iodine	20 grains
Nitric acid	20 drops
Hydrochloric acid	20 "

This, applied to any silver stain, and followed by cyanide of potassium or hyposulphite of soda, at once removes all traces. Apply the first solution to the stained linen by means of a camel's-hair pencil, the black stain will become yellow; now apply a solution of hypo or cyanide, and the stain will quickly disappear. Then rinse the place thoroughly with water.

D. W.—A portrait lens may be used for landscapes, but if objects on many different planes are to be defined, it will require stopping down considerably. 2. The value of a negative depends upon so many things that no definite, or satisfactory, answer can be given.

TYRO.—A floating scum of metallic silver formed during development, or a quick decomposition of the developer, throwing down the silver in a dark powdery form, may arise from several causes; such as the presence of some impurity in the nitrate bath, too little acid in the developer, under-exposure and protracted development, or the presence of some white light in the dark room.—2. Same as above. 3. A rusty appearance at the edge of the plate is most probably fog from imperfectly cleaned glasses. 4. When Prussian blue is formed on your plate it is because the iron was not sufficiently washed away before applying the cyanide. A porous and absorbent collodion requires much more carefully washing to remove each solution than a horny one. 5. Brilliancy in the negative depends upon the harmonious co-operation of many causes too lengthy to detail here; read a series of articles entitled "Iron Negatives and Brilliant Prints," which appeared in the Fifth Volume of the PHOTOGRAPHIC NEWS. From what you state, either your bath is out of order, or you develop too long.

6. It is very difficult indeed to distinguish at all times between the fogging caused by impure chemicals, and that by diffused light; nevertheless, as a rule, the surface deposit indicates that the chemicals are at fault.

R. (GLAER.)—It is quite unimportant whether your ground glass be thick or thin, as the image falls on the anterior surface. In the choice of a lens we prefer maker No. 2. It is necessary to tone in a dark room, as the prints would, of course, be injured by exposure to white light; but it is not important that the room be as free from white light as that for developing negatives. The two modes of spelling Voigtlander and Son, both refer to the same firm.

A. M.—There are various modes of obtaining metallic silver from the chloride, but perhaps the simplest is to reduce by heat in crucible by the aid of a flux. First carefully wash the chloride to remove all impurities, then dry and add twice its weight of a mixture of carbonates of potash and soda, or of carbonate of soda and of borax, place in a crucible, and apply a bright red heat for about an hour.

H. C. M.—Your question as to the best paper for enlarged pictures is a very indefinite one, as you do not state what mode of enlarging is to be employed. If you mean prints from enlarged negatives any paper which gives good results for small negatives will do; if to enlarge by means of the solar camera, printing out, then any good paper for other purposes will do; but if you mean enlarging and developing the print, then a paper especially suited to the results you require should be used. Towgood's paper gives generally the most vigorous, Turner's more half-tone; the Saxe and Rive papers more half-tone still. Some operators prefer drawing paper, as being less liable to tear in the washing. As regards the photographic result of any of these papers much will depend on the salt employed in the first preparation.

VEADANT.—You cannot do better than you propose, nor can you secure greater cheapness without sacrifice of quality. 2. No stereo lens will not cover anything like a $7\frac{1}{2}$ by $4\frac{1}{2}$ plate; using the front lens of the combination will give you a little larger field, but not to cover the plate in question. 3. The simplest shutter for your purpose is the flap shutter made by Dallmeyer. 4. Mr. Robison, of Leamington, is a professional photographer.

SR DEXIS.—A good bromo-iodized collodion, without any addition to it, is suitable for taking interiors. 2. There is no remedy for a collodion which has too much water, except mixing it off with a better sample. Keeping out of the bath until it is well set, will decrease its tendency to reticulate. Exposing long enough, so as not to need to force the development or intensifying, will also decrease that tendency.

AN AMATEUR.—When you refer to the albumen going into streaks, we presume you are referring to the process of albumenizing paper, although you do not say so. Streaks in albumenizing will occur from many causes, the most prominent of which is unskilful manipulation. The albumen not being well beaten up, or not having the germs removed would cause it. Too long floating the paper will sometimes cause it; and it will arise from faults in the paper or sizing, causing unequal absorption of the albumen. Whatever the state of the weather, albumenizing should be conducted in a room at a high temperature, at least 70° or 80° Fah.

D. D., Brighton.—We have not seen the portraits resembling postage-stamps to which you refer. It is not improbable that they may become popular, but we cannot speak with much certainty. Any quarter-plate or stereo-scope lens will doubtless answer; the capability of taking twelve heads on one plate does not belong to the lens but to the camera, or rather to the dark slide containing the plate, which must revolve so as to bring the various portions of the plate successively opposite the lens. Mr. Cox, of St. Mark Street, exhibited in the International Exhibition a contrivance for the

purpose. Of course a series of small lenses, properly arranged, would answer the same purpose.

C. W.—Both or either will answer for stereo interiors and give perpendicular marginal lines. We prefer the latter of the two, both for general and instantaneous work.

JOHN INSKIP.—The instantaneous portrait of a baby received is very pleasing indeed, and quite successful as a picture. We shall have much pleasure in publishing an account of your method of securing such effects.

W. B. M.—We prefer the first you name. 2. The No. 1 triple is very suitable for groups in a good light, but would be slow in a bad light. 3. The No. 2 B of the maker you name may be used with full aperture for card portraits, and its advantage over the No. 1 B is much greater rapidly, as the latter must be used with a much smaller stop to get as good definition. The image is moreover, rounder, and has its different planes in more perfect focus. But we have seen excellent pictures taken with both lenses. 4. See article on another page on the double salt of iron and ammonia. It is easily made by dissolving two parts of the ordinary protosulphate of iron and one part of sulphate of ammonia.

S. W. B.—We will give our opinion of a picture if you forward it. See answer above as to your glass.

L. L. II.—You do not state the focus of your lenses nor the size of the stop, both most important elements in forming an estimate of the extent of definition which ought to be expected. Speaking generally, the definition is not unsatisfactory for a "stereo lens" with "large stop." Both pictures, however, are not equally sharp, and if they have received justice in manipulating the lenses are not quite coincident in focus.

B. B.—If you are using the same paper, the same silver bath of the same strength, and the same class of negatives, the same kind of toning bath as before, and yet fail with the same treatment to get as good prints, it is very difficult to make a suggestion. Are you certain the bath is not impoverished and low in silver? Are you sure the paper is the same? Are the negatives brilliant? Is your toning bath old or exhausted? Send us one of the good and one of the bad prints. 2. In Mr. Blanchard's hands the plates in question keep four hours in summer, and twenty-four hours in winter.

J. L.—Of those you name, probably, No. 2.

GOODWYN LEWIS.—As a rule, it is necessary to register a print from each distinct negative, unless they are in all respects identical. In regard to a copy of a work of art, probably the registration of a negative of one size may be sufficient; but, if you are anxious to make the copyright secure, it is best, in regard to a doubtful subject, to be on the safe side. We have handed your note and stamps to our publisher, who will send the form. All communications on the actual business of registration should be addressed to him.

L. S.—Render your nitrate bath neutral; the presence of nitric acid is favourable to mealiness. Use brilliant negatives; wash well in distilled water before toning, or try a bath of acetate of soda first. Let your toning solution be made a week before using it. Tone slowly. If these fail, try another sample of paper.

JUSTITIA.—We have carefully examined your specimens, and the model of the glass room. Much better pictures can unquestionably be obtained in such a room. The first characteristic which strikes us in the prints is the presence of too much diffused light. You have a large glass room with light struggling in from many directions. The pictures require more concentration of light from one source. Remove all light from the end, which should be black. In specimen No. 1, all modelling is destroyed by front light. The same is true of No. 2 and 3. Have dark blinds on the shaded side, and on the lighted side try reducing the extent, or space, through which light is admitted. The chemical part of your work is right enough; but there is a tendency to under-exposure in all the pictures. The definition is very poor indeed, and tends largely to give the unsatisfactory modelling of which you complain. There is no crispness or decision anywhere, and the best possible lighting in card pictures will not give good modelling with a lens which defines badly. See diagram of Mr. Rejlander's room, and also his remarks on it last week.

G. C.—See article on "Glass Rooms" in our YEAR BOOK OF PHOTOGRAPHY for 1863. Also further remarks on the subject in the PHOTOGRAPHIC NEWS for March 6th and April 2nd of this year.

SEA-SIDE.—Give considerably more exposure, and work with a weak iron solution freely acidified with acetic acid. Take care to get the shadows clean and transparent, with some slight touches of bare glass. If you intensify after fixing, first apply a solution of iodine to the film as recommended in our ALMANAC. Take care to prevent diffused light entering your camera.

C. F. WATSON writes to inform us that grey vignettes, or vignettes softening into a tint instead of into white paper, were taken by himself and brother in 1861, long before Mr. Harner wrote on the subject. It is very possible they did, and very possible that they did them well. We produced vignettes in the same style many years before that, and so, doubtless, have others. We again repeat, Mr. Harner made no claims of discovery on the subject, but he carried out with great skill, and with great variety of effect, a familiar idea, and then published for the benefit of brother photographers a detail of his ingenious manipulations. Several Correspondents in our next.

THE NEW IRON DEVELOPER.

As the double salt of iron and ammonia seems likely to become a favourite developer, a few more words on the subject may not be uninteresting. We have, in the first place, a slight reclamation to make. The suggestion for its use is almost universally accredited, by the photographic press at home and abroad, to M. Meynier. This gentleman called attention to its use at a meeting of the Marseilles Photographic Society, held on the 8th of October, 1862. Two months previous to that date, this salt had been recommended as a developer by the *Photographic News*. On page 374 of our last volume, published on the 8th of August, 1862, the nature, properties, and manufacture of the salt are fully described, and its use as a developer in place of the ordinary protosulphate recommended. That the suggestion might be quite original with M. Meynier we do not at all doubt, nor that it has received a considerable impetus from his recommendation. The matter is not a very important one to reclaim; but since the salt will very probably come into general use, it is worth while placing these facts, as to its first application, on record.

As to its value as a developing agent, opinions generally seem, as we have said, in its favour; but as to the precise amount of excellence there appears to be some uncertainty. In our own hands it has a slight advantage over the ordinary iron developer in giving cleaner shadows and intenser lights; but we have not found any palpable difference in the length of exposure required by the plate in the camera caused by its use: some of our friends, on the contrary, are decidedly of opinion that it permits a shorter exposure in the camera, and yields a very harmonious image with such short exposure. The unquestionable advantage it possesses is that the crystals, even when kept in loosely corked bottles, do not become per-oxidized. In solution, however, a small portion of a per-salt is formed, so that the developer is not deprived of the qualities, regarded as valuable by many photographers, which the presence of a small amount of the per-sulphate produces.

The double sulphate is very easily prepared; two parts of sulphate of iron and one part of sulphate of ammonia are dissolved in, say four parts of water. The solution is then gently evaporated, over a water bath is best, until signs of crystallization are seen, when the vessel is put aside to cool without disturbance, when the double salt is formed in beautifully clean and clear crystals. For those of our readers who are wishful to try its effect and have not the opportunity of procuring it, the manufacture is a simple matter, and both the salts of which it is formed may be had of any chemist. For experiment it is not necessary to crystallize the double salt, the solution itself may be filtered, and with the proper addition of acetic acid, used at once.

As regards its energy as a developer, it must be borne in mind that, theoretically at least, the double salt is not so active as the same weight of ordinary protosulphate, thirty

grains of the double salt being equivalent in energy to about twenty of the ordinary protosulphate.

As we have received many inquiries as to the price of the double salt of iron and ammonia, and where it may be obtained, we may mention that it will shortly be kept by photographic chemists generally, and sold at a price not much higher than the ordinary protosulphate of iron. We may also add that we have recently received from Bailey and Son a very fine sample, which is put up in pound bottles, which are sold for eighteen pence each.

AMMONIA IN PRINTING.

FROM recent American intelligence it would appear that the *dernier mot* on the value of ammonia in printing has not yet been spoken. Mr. H. T. Anthony announces a discovery that by using a solution of moist oxide of silver in a solution of nitrate of ammonia, for exciting albumenized paper, an enormous saving of silver can be effected, whilst rapid printing, easy toning, and good results are also secured. Mr. F. F. Thompson states in the *Amateur Photographic Print* that he has seen some prints by Mr. Anthony on paper sensitized with a silver bath equivalent to *five grains* of nitrate of silver to the ounce of water, and that they were in all respects excellent.

Mr. Anthony, writing on the subject to *Humphrey's Journal*, says:—

The solution used by me could not have been of the strength of twenty grains of nitrate of silver to the ounce of water, yet with it I made a very excellent print which toned very readily, yielding fine black tones and pure whites. The paper is, besides, very sensitive and prints very quickly. My chemist is now making an examination of the matter, and we shall soon have some of the compound for sale. In the meantime I would suggest to photographers to try a 2-drachm solution of nitrate of ammonia, to which as much moist oxide of silver should be added as it could dissolve.

It will be seen that no allusion is here made to the proportion of chloride used in preparing the paper, a somewhat important element in the question. The subject is, however, interesting, and we shall duly apprise our readers of the further developments of this subject.

AMATEUR PHOTOGRAPHY IN AMERICA.

AMATEUR photography has been progressing of late amongst our friends in the States. In point of numbers they are still, probably, far behind this country; but what is lacking in numbers is made up in enthusiasm. Amongst other illustrations of this enthusiasm, we may mention the recent establishment of a periodical, entitled *The Amateur Photographic Print*, the editor, printer, and publisher of which is our esteemed correspondent, Mr. F. F. Thompson, the late Secretary of the American Society. Three numbers of the periodical are now before us, which are full of fun and in-

formation, a few samples of which we propose to lay before our readers. To indicate exactly the position of the new periodical, we make a brief extract from its prospectus:—

The *Amateur Photographic Print* is just what the title indicates. It is issued for the benefit of the members of the Club, and for their mutual edification. It is printed and issued by the secretary solely. He sets the type, locks the form, and prints the sheet on a private press in his own photographic "den." The publisher being purely an amateur, of the laziest kind, the precise days of issue will depend very much on time and pleasure; but he intends to issue the Photographic Print monthly, if not too lazy.

In fact, this is to be a purely independent sheet. The terms of subscription are of the most liberal kind; filthy lucre being entirely disregarded, and the whole number of subscribers being on the free list. Only the members of the Club will be recognised as having a right to blow-up the Editor, and they, in return for this privilege, will be expected to keep THE PRESS alive by frequent contributions. Short articles written to the point will have the preference. Short, because our compositor, being a green hand, would be "stumped" with a long job, and the d—l (we mean the one in our office) can't find room on the press for but a limited amount of matter.

The first article is headed "Photographic Quarrels," in which provision is made for the possible escapades of some of our pugnacious friends. We make a brief extract:—

PHOTOGRAPHIC QUARRELS.

"No quarrelling allowed." This notice appears in the "studio" of one of our enthusiastic dog-fanciers, and if Carlo or Towzer grow uncivilly, they are turned out of decent company. We notice that this little world, only twenty-five thousand miles broad, is not wide enough for more than one photographic paper to swing clear in, without striking against some other one, and so we expect, when we say black is black, or white is white, to hurt the feelings of somebody, and start a controversy. We say we expect this, and therefore we announce our intention of sailing the heliographic ocean of the universe alone, regardless of all small potato concerns that presume to disagree with us or get in our way.

With the second number of the *Print* a presentation photograph was issued by the Editor, in regard to which he observes:—"We do not wish to kill any of the other journals with envy, nor do we wish to kill ourselves with braggadocio, but we think that our presentation print 'knocks the chips' from anything yet done." This number, which contains an article on "Brass Toning" by the Editor, concludes with a somewhat plaintive appeal to contributors. The Editor thus addresses his friends:—

Gentlemen of the Amateur Photographic Exchange Club! We have not had one line for the *Print* from any of you. But two of you have even spoken cheerfully to us. As our President of the United States would say, "That reminds us of a little story."

In New York three policemen were sent to examine the Twenty-seventh Street haunted house. One was posted at each door, while Jim, the third, was to go up stairs to find the ghost. He expected to hear unearthly noises and horrible sounds; but he was disappointed. The silence was terrible. The gloom was deepening, and Jim shook with fear. His teeth chattered as he turned the stair head, but still there was that horrible darkness; that terrible silence. He peeped over the banisters and saw the guard in the front door. He could stand it no longer. He croaked out in a voice hoarse with terror, "Say! Fellars! Whistle or suthin', or there'll be a dead perlice-man up here."

Gentlemen of the Club! Jim needed encouragement. You are out on the sidewalk of the photographic world, with your hands in your pockets, looking at life in the street, while we are groping alone in the dark gloom of Journalism in dreadful silence.

Gentlemen of the Club!! Whistle or something! or there'll be a dead *Print* around here.

The third number opens with an article on toning by Professor Hines, in which he refers to Mr. Thompson's claims on behalf of "brass" in toning, and states that his toning solutions work better when copper is present. An article on the Amateur Photographic Exchange Club states that the "day is near when Brother Jonathan will enjoy amateur photography as much as John Bull." The writer anticipates that after the peace shall have been established the numbers will increase by hundreds instead of tens as hitherto. We scarcely imagine that professional photographers will endorse the same writer's reasoning in the following remarks:—

An amateur is generally a better workman than a professional, for the reason that it is not his *labour* but his *amusement*; and he can spend as much time over a single picture as is requisite to make it perfect. He can travel where and when he will, and has the widest choice of subjects. He has no living to make, no grumbling customers to hurry him up, no one to please save himself and his wife.

A presentation print which accompanies the third number is an etching on collodion, by Professor Rood, printed photographically by the Editor, illustrating a paper by the latter gentleman, read before the American Society. The mod of

producing these etchings given by Professor Rood is interesting. He says:—

The plates are made by Mr. Enenger's process. The glass plate is coated with an adherent collodion (sensitized with the alkaline iodides, and rather old), placed in the bath as usual, removed from it, and held in the hand before a window for one or two minutes. It is then developed with sulphate of iron, and well washed and dried. It does not go into the hypo.

The drawing more or less complete, is made on letter paper, and the outline traced through this on the plate, using common tracing paper and a small rounded point; or the drawing, if it be slight, can be made directly on the plate with a pale wash of india ink.

The plate is then placed on black velvet, collodion side up, and the drawing made with a common needle, fine or not as may be desired, which is set in a wooden handle.

The manipulation is much the same as in making a drawing with a pen on paper; and as every line drawn by the needle shows as a black line on a white ground, the effect can be judged during the operation. When the etching is finished it is varnished, a proof print struck off, and necessary alterations in the plate are made.

Properly speaking, a complete copying on paper in light and shade should first be made, and the etching derived from this; though in the etchings which I have executed, and which were sent to some of the Club, this was not done, nearly all the work being made at once with the needle.

The object of the *Amateur Photographic Print* appears to be fun, as much as photography. It succeeds well in combining both, and we hope again to draw from its pages.

Critical Notices.

A TREATISE ON POSITIVE PRINTING. By THOMAS SUTTON, B.A. London. LAMPRAY, TIBBITTS, and Co.

A FAMILIAR and intelligent treatise on the production of positive prints is certain of a ready welcome from all photographers. Notwithstanding the acknowledged importance of printing, and the many unacknowledged difficulties connected with the subject, there have been but few treatises on the subject, and no instruction book, that we remember, devoted solely to printing. Mr. Sutton's pamphlet, as announced in the preface, "has been written chiefly as a guide to those who use the patent albumenized paper, which is sized with india-rubber before using the albumen." But it is something considerably more than such a guide: it is a thoroughly intelligent and interesting treatise on the general subject of printing, which no photographer can read without profit. The whole subject is lucidly discussed, and the author's own practical conclusions clearly stated. We recommend every one of our readers to possess this little work.

THE ISLE OF WIGHT. A Series of Views Photographed by ROBERT GORDON, Bembridge, I. W.

This is by far the best and most complete series of views of this charming island we have seen. There are few places more abounding with subjects for the camera, in the shape of wood and water, rustic cottages, leafy lanes, sylvan nooks, &c., &c., and few which have hitherto received so little justice. In Mr. Gordon's series, however, we find many very excellent photographs, and, what is better, many very beautiful pictures; the point of view well selected, the photograph harmonious, free from chalky lights or black shadows, and without a mass of white paper in place of a sky.

In many of these pictures, which are, we should remark, on twelve by ten plates, a natural sky with pleasing clouds is secured, adding immensely to the value of the pictorial result. The means by which this is effected on large plates is, as we recently stated, by the use of a one-grain iron solution, prior to the application of the regular developer, consisting of eight grains of protosulphate, and twenty minims of acetic acid to an ounce of water.

We have not space to notice each picture in detail, but may mention a few which we consider especially good. "Little Jane's Cottage," a spot rendered famous by the Rev. Leigh Richmond as the residence of the "Dairyman's Daughter," is a very charming photograph, brilliant, yet soft and harmonious, with an atmospheric sky and indefinitely indicated clouds; a rustic figure just entering the

garden gives life to the picture. Several views of, and about, Bonchurch, are very fine; we may especially mention a lane scene, with figures, as an exceedingly fine picture. A View of Ventnor is a very perfect photograph; the mass of white houses in the blazing light, are not chalky, the water is transparent, and the dark rocks in the foreground are full of detail. The "Crab Inn," Shanklin, the "Keeper's Cottage," the "Old Manor House," "Yaverland Church," and others, are all excellent pictures. "The Village Lane" is a very pleasing picture, and by the sacrifice of about three inches at the right, might be made perfect. In the majority of the pictures before us, Mr. Gordon has achieved complete success, and rendered justice to the charming scenes he has depicted.

HER MAJESTY THE QUEEN. Photographed from Life by the late Mr. C. CLIFFORD of Madrid.

This is, in many respects, one of the most interesting portraits of the Queen ever published. It was photographed in the year 1861, by the late Mr. C. Clifford, an able English photographer, residing at Madrid, who was entrusted by the Queen of Spain with a photograph, as a present to the Queen of England, together with a request that Her British Majesty would send in return her portrait. Mr. Clifford then received Her Majesty's command to produce the present photograph. It is probable that Mr. Clifford was scarcely prepared for this honour; he had, however, recourse to Mr. Ross for assistance, who furnished him with a suitable lens, and in the middle of November, Her Majesty standing some distance within the orangery, the only light reaching her being that passing through the open doors in front, the camera out on the terrace, he succeeded in obtaining a very good negative. The portrait gave Her Majesty and the Prince Consort so much satisfaction, that they gave Mr. Clifford permission to publish it; a step which has been delayed, however, until the passing of the new Copyright Act should protect the picture from piracy.

The size of the picture is a trifle under 12×10 on a mount 24×18 . Her Majesty stands with folded arms, arrayed in semi-regal costume; the dress and train being of handsome black watered silk; she also wears a coronet of diamonds.

The photograph is, considering the circumstances under which it was produced, amazingly perfect. Something, perhaps, is left to desire in the matter of expression, and the background furnished by the interior of the room, having been stopped out, leaves this part of the picture less satisfactory than might have been desired. The picture is, nevertheless, the most imposing portrait of Her Majesty which has been published; the only photograph, indeed, which is suitable for framing, and will, doubtless, have a very large circulation.

Scientific Gossip.

PREPARATION OF ALCOHOL FROM COAL GAS.

REMOURS have lately been heard in the chemical world of a discovery by a young French chemist of a process of manufacturing alcohol, which, if successful, will entirely revolutionise this branch of trade and will confer a great benefit on photographers and others who require this solvent for business or experimental purposes. The fortunate discoverer is a M. Cotelte, and the raw material from which he evokes such a magical result is nothing more or less than coal gas! Coal gas, as our readers doubtless know, is a highly complex mixture of various gases and vapours, containing amongst others, hydrogen, olefiant gas and other hydrocarbons, light carburetted hydrogen, carbonic oxide, carbonic acid, sulphuretted hydrogen, ammonia, oxygen, and nitrogen. The first three are the only valuable constituents, the others being impurities present in comparatively small quantities. The ingredient utilized by M. Cotelte is the olefiant gas, so called

from its property of forming an oil with chlorine and bromine. The formula of olefiant gas is C_2H_4 , and that of alcohol is C_2H_6O ; they only differ therefore by H_2O , which is the same as $2H$, or two equivalents of water. If, therefore, olefiant gas can be persuaded to assimilate to itself the elements of two equivalents of water, the thing is done. This synthetical branch of chemistry has of late years received great attention at the hands of Gerhardt, Wurtz, Berthelot and others, and in fact the problem of effecting the hydration or olefiant gas by means of sulphuric acid was some time ago realized by the latter chemist. Nobody doubts that sulphuric acid is capable of fulfilling the paradoxical functions of hydrating olefiant, and yet of dehydrating alcohols (as in the ether-making process), according to the conditions of the experiment; and it is tolerably certain that, by working on a sufficiently large scale, alcohol might be prepared in quantity by a modification of Berthelot's process; but that it could be done with anything like the economy claimed by M. Cotelte, we utterly deny. Berthelot, if we remember rightly, caused the olefiant gas to assimilate to itself the elements of water, somewhat as follows:—Sulphuric acid was placed at the bottom of a bottle, and the upper part was filled with olefiant gas. The stopper was then lightly inserted, and the bottle was fastened to the vibrating frame of a saw-mill, where it could be violently agitated day and night for a considerable time. After an immense number of shakes, the olefiant was found to have been absorbed by the sulphuric acid, in the form of sulphovinic acid. This was diluted, and the alcohol obtained from it by distillation. This is almost identically the process now about to be introduced at St. Quentin. The patentee speaks of several different modes of producing intimate contact of coal gas with sulphuric acid. The first is, by means of a pump, to discharge the acid in the form of rain into a leaden receiver containing the gas; the second is a more complex method of operating, but on the same principle; the third is to procure absorption by pressure, as in preparing soda water; and the fourth consists in placing the sulphuric acid in the form of vapour in contact with the gas. It is evident that very little ingenuity is shown in the methods of causing intimate contact between the gas and acid; they are all inferior to the one originally employed by Berthelot, and considering that in his small experiment it was necessary to give the mixture 53,000 shakes before combination was effected, there is every reason to assume that by Cotelte's processes, and on the scale necessary for a manufacturing operation, only a very small portion of the olefiant present in the coal gas will become hydrated. Two other objections strike us as being impediments to the successful working of the process; one is, that coal gas seldom contains more than three or four per cent. of olefiant gas, and every one knows how dilution interferes with chemical action of this sort; another objection is that if the gas is used purified, some of the olefiant will be lost in the sulphuric acid used in the preliminary purification, whilst if the coal gas is employed in its crude, impure state, the ammonia and other bases which it contains will unite with the sulphuric acid, and introduce complications into the after processes. Another difficulty is where to procure the coal gas. Of course, Mr. Cotelte proposes to use the gas at a gas-works, and after passing it through his apparatus, to return it to the gas company for circulation to their customers; or perhaps the manufacture of gas for lighting purposes is to be carried on simultaneously with that of alcohol. In any case, we fear the consumers of the gas will be inclined to grumble at its inferior illuminating quality if Mr. Cotelte has succeeded in depriving it of its olefiant, seeing that this gas is one of the principal illuminating agents of ordinary coal gas.

Besides these objections, which might, perhaps, be got over, there are the more serious ones connected with the manufacturing process; there are to be pumps constantly working in sulphuric acid of almost the strength of oil of vitriol, and the wear and tear of these must be enormous; then again the

acid, after being diluted sufficiently to allow of the alcohol being distilled off, is to be concentrated by heat until it is of the proper density for a subsequent employment. The patentee, on this part of the operation, says that great economy will be found in this source, the sulphuric acid may serve almost indefinitely.

Now the concentration of this sulphuric acid involves the establishment of another factory on a large scale, for the quantity of strong acid to be employed is considerable. M. Cotelte himself admits that it requires about $1\frac{1}{4}$ cwt. of acid to produce one gallon of alcohol, and we may be sure that he has stated the minimum quantity; but this $1\frac{1}{4}$ cwt. has to be diluted with five times its bulk of water, and then this excess of water has to be evaporated down again. The costs of fuel for this will be considerable, and when we add to this the expense of leaden pans, and the wages, &c., we venture to say that the production of alcohol by Cotelte's process, at anything like Cotelte's price (10d. or 1s. per gallon) is a chemical impossibility. Still, it may be possible when the process has been tried on a large scale, and the difficulties as they arise met and combated with the skill which is sure to be applied when the pocket is concerned, to prepare alcohol at a somewhat higher price, but still leaving a profit. On this view of the question, the photographer will have other things to consider. An alcohol built up from its elements ought to be absolutely pure and free from every deleterious empyreuma. In this case the introduction of hydrated olefiant gas into commerce will be a great boon to all practising the art. On the other hand, it is very probable that carbonaceous impurities, sulphur and other things, will remain with the sulphuric acid, and, being liberated with the alcohol, will render this highly impure, and unfit to be used for anything but rough manufacturing processes. Of the two suppositions the latter is by far the most likely, and if it should turn out that this is the case it will be a still further objection to the "process, Cotelte."

IMPRESSIONS ON CHROMATE OF LEAD.

BY DR. T. L. PHIPSON, F.C.S., &C.

A FEW days ago I remarked upon a table in my laboratory a sheet of yellow glazed paper (coloured on one side only), which had very distinctly received the impression of a printed page that had been lying for some time upon it. The black characters of the printed page were here reproduced in *white* upon the yellow ground. I immediately analyzed the paper to know what the colouring matter consisted of, and found it to be chromate of lead. The paper was, moreover, soiled by sulphuretted hydrogen gas, so often required in the analysis of minerals, and which, in the best ventilated laboratories, does not fail, now and then, to attack uncovered salts of lead, copper, &c. These circumstances gave me the key to the mystery: the white characters were evidently formed of sulphate of lead, produced by the oxydation of the sulphuretted hydrogen; this oxydation only occurring in contact with the charcoal of the printed characters, and the oxygen being probably derived from the chromate of lead.

COPYING AND ENLARGING.

BY A. MACNAB.*

As the copying and enlarging of pictures have ever formed a very important element of employment to a numerous class of operators, permit me to introduce to your notice a few simple and practical details bearing upon the subject. That it is of importance will at once be admitted, on the score of the large and increasing demand in this direction, more particularly since the introduction of card pictures, and from the fact of small pictures admitting of being enlarged without the distortion consequent upon using large lenses, so much spoken against by Sir David Brewster. That such enlargements are

appreciated by the public is rendered obvious by the recent call for solar camera enlargements, which, although some optical questions remain unsettled with regard to the instrument by which they are produced, do not fail to become exceedingly attractive, and which, ere long, it is anticipated, will throw into the shade their Lilliputian originators; and whilst advertent to those pictures, we must for a moment refer to the pleasure with which we listened to the paper read to the members of this Association on such enlargements, and so ably illustrated by Mr. Stuart, and still more recently by Mr. Douglas, at our late conversazione. The following remarks are not intended to detract from or impugn the merits of that class of pictures, but to bring before your notice a different instrument, which serves as a medium by which parties not possessed of a solar camera may by its aid effect enlargements to a considerable extent, without loss of detail or fear of distortion, whilst it has the advantage of not requiring direct sunshine, but can be wrought out in a quiet diffused light.

This method is not advanced as new, having long since been applied; but as many are not yet aware of its value, and the immense facilities it affords for the reproduction of negatives from one single sitting, it occurs to me that this subject will form a companion paper to those preceding. In business, as a matter of course, we wish to find the best and readiest method of attaining our object; and in thus sketching my mode of proceeding, I do not want you for a moment to suppose that it is the most perfect, but simply as I have found it in my experience—the most suitable and convenient. My first attempts in this direction caused me much annoyance; allow me for a moment to refer to it. A small 1-6 plate had to be enlarged to 1-1 size plate. The picture was put up in order to be copied, which I proceeded to do with a whole plate, "Sheppard" lens. After focussing the image sharp upon the screen, and, as I thought, in condition to make a good picture, conceive my chagrin, after exposing and developing the image, to find a terribly blurred and confused abortion—if such a phrase can be applied to a conception of this sort. What could be wrong? Had the camera moved, or the plate got out of its place, that the resultant picture should be so far from sharp? Another and another plate was tried, with a like success, until I had to abandon it in despair. Another of my difficulties was in the arrangements of the camera, and the proper adjustment of the picture to the plane of the axis of the lens. Much time was taken up in getting the one parallel with the other. After much consideration, it struck me that a very simple way of overcoming this obstacle was, to construct a long board, on which to place the camera, having an upright grooved frame at one extremity to admit of a cell, similar to that used for exposure. Into this cell place the picture to be copied, arranging the camera in position, and at the right distance on the board. We will now suppose that the picture has to be copied size for size, or under. In most cases I use a Grubb card, No. 3 lens, well stopped down. Glass positives are generally difficult to manage, and few covet this kind of work from the unsatisfactory results often obtained. Should it be a glass positive to be copied, in which the clothes are black and underdone, with the shadows strongly marked upon the face, the exposure will require to be prolonged an unusual length of time, otherwise the result will be far from satisfactory, with a highly-iodized and full-bodied collodion in a good working bath, in such a case, will yield the best return for the labour expended. Overdone and well-defined positives usually give good results, and not unfrequently the copy is superior, in a photographic point of view, to the original. In copying daguerrotypes, first free the surface from the fine particles of dust which usually adhere to pictures of this description, with a soft camel-hair brush; if the positive is somewhat faded, showing a blue or brown haze on the surface, a weak solution of cyanide of potassium carefully flowed over it will remove the oxydation, and render it more suitable for copying; this done, observe the way the plate has been buffed, allow the striping to run perpendi-

* Read before the Glasgow Photographic Association, on Thursday, April 2, 1863.

cular to the front of the lens; this is important to free the picture from the buffing lines observable on the original; failing this precaution, these streaks become painfully distinct and offensive. If your camera has a swing back, be careful that it is set fair and plumb, or your copy will be out of proportion. A little attention at this stage will save much trouble and vexation, not to speak of a ruffled temper. Adjust to copy for proper size, and take precaution to guard against reflected light, by covering the camera and mounting the lens with dull black cloth, or, better still, velvet; allow a full flood of northern light to fall upon the plate; or it may be sometimes an advantage to have a blaze of sunshine: much depends on the subjects to be copied; the same rule applying to the daguerreotype as to the collodion positive, in the case of its being underdone or well defined. There are many other minor points of detail in the manipulation upon which your discretion must be brought to bear, according to the circumstances which may present themselves, which, in a paper of this kind, would occupy too much time and space to particularise and enumerate; but one advantage in this really simple and inexpensive mode is, that it can be put up and taken down in less than two minutes, should you be disturbed in your copying, and required to leave off and take sittings. I am presuming you have but one glass house for operating. By using a cell, or holder, for the plate to be copied, you can at pleasure expose or cover it up, and put it past in a place of safety till a more favourable opportunity offers for the successful completion.

Since the introduction of the cards, the demand for direct large pictures has been very limited, such orders now being like "angels' visits, few and far between;" yet, from the cards a new demand has arisen, and inquiries are made, such as: Is it not possible to give us large pictures as beautiful and as truthful as those charming little miniatures, so that they may be coloured and made suitable to hang in our drawing-rooms? I found it rather a difficult matter to meet such a demand at first, from the fact of not having the necessary apparatus. Some there are who can work with almost anything—construct a clock, it may be, with a pen-knife, or perform several mechanical feats similar, with indifferent materials; but I think it must be admitted by all, that good instruments are indispensable to successful manipulation. It is an axiom that "what is worth doing, is worth doing well." We may often entertain the notion, and yet have great difficulty in its realization. Such I found to be the case in my first effort to produce large pictures from small ones; and here I must add, that of all the professions that I know of, requiring the operator to have his wits about him, there is none so much so as the photographer, as he must possess an aptitude to suit himself to the varied circumstances which are continually presenting themselves, in ever-changing, never-ending, forms and phases, and which no rule can well define. Perception in a high degree, to which we must add a thorough care and watchful attention, in regard to those mementoes of the "gone, for ever gone," entrusted to his charge for copying, &c. Such qualities are essentially requisite for the successful prosecution of the various branches of photographic reproduction, as the slightest inattention to those invaluable keepsakes, may often cause irreparable discomfort to those to whom they may belong. It often happens that such do not escape scatheless. You have many assistants, and when anything goes wrong, all are more or less ignorant of the cause. The knowledge of such accidents having occurred, often prevents parties from allowing those souvenirs to be copied, owing to the risk which has to be run in their attainment. As an instance of this, I may mention it was once my lot to observe, whilst in the gallery of a photographic friend, a lady whose face wore the aspect of the most earnest anxiety. After her departure, I learned that she had come for the purpose of having a daguerreotype copied. The engagements of the gentleman prevented him from seeing the lady. Day after day she had called, but persisted in not allowing any one to handle the much-prized picture, or to communicate

her business to any in the establishment. Day after day did she toil, climbing up those long and weary stairs leading to his studio, till at length she inquired if Mr.— was a myth that could never be seen. Having succeeded in obtaining an interview with the artist, it was arranged to copy the picture, during the manipulation of which she sat patient and uncomplaining, never for a moment allowing the picture to leave her sight until the operation was completed. Pardon this digression.

With very crude materials I made one or two abortive efforts to produce large pictures direct from small prints, but this mode I eventually discarded for the following simple method; let me remark, "*en passant*," that the first I produced were done in the most rude and extemporary manner, to find how far the system might be successful in my hands previous to getting a more complete and systematic apparatus. The plan worked well, and my wish to enlarge from small negatives was thus realized.

METHOD.

Take an unvarnished "carte de visite" negative, or negative of any sort unvarnished requiring to be enlarged; place it in the cell holder, with figure inverted, collodion film towards the lens, fix it in the slide with opaque gum paper so that no light be admitted, save passing through the negative, with the slide up; turn an enlarging camera with lens reversed, or end for end. I am supposing that a common portrait combination is to be used. Draw back your camera until the image appear of the desired size upon the ground glass; stop down to give sharpness; have it so arranged that it is placed against the clear sky; where this cannot be done, place a sheet of white paper against the window immediately in front of the negative, at a distance of at least twelve inches, that it may be out of focus. If the negative be a dense one, use a thin collodion, a good positive highly bromized and free from crapy lines; give a long exposure, and develop with strong iron, say thirty grains to the ounce of water, continue to develop this plate until there is detail all over the face. Don't be afraid of overdoing the dress. Clear the iodide off with cyanide and examine the plate as to the suitability of its being used as a transparency. If the negative is thin and full of detail, much shorter exposure will suffice, with a developer not stronger than fifteen grains to the ounce of water. In all cases the character of your negative must regulate the time of exposure; and the careful timing of the plate will greatly modify your transparency. When you have obtained a transparency, dry it, and after removing the negative, put it into the cell before-mentioned, observing the same precaution as with the negative, or, as the glass is now transparent, you may have a chimney-top or window stuck into the body of your subject. Again, adjust the camera to get the image the required size upon the focussing-screen; take a plate with good negative collodion the usual way, but shorten your exposure to about one-fourth of the time required for the transparency, although the enlargement may be considerable. These remarks equally apply in copying stereoscopic transparencies or slides for the magic lantern. I am indebted to the kindness of Mr. Spencer for the use of two plates that I might illustrate the subjects of this paper, and show the capabilities of this method for the reproduction of negatives. It would be a gratuitous statement were I to allow you to believe that this system is free from trouble, or that you can expect work as perfect by it as a negative directly from the subject (could that be obtained without distortion), or by the solar camera, the inequality of the glass, the imperfection of the collodion film, dust, spots, comets, and numerous other accidents being all fatal to perfect success. On the other hand, the advantages afforded are indeed considerable—first, that of obtaining large negatives from small ones, and in any number, from one sitting, this alone being exceedingly serviceable where pictures of popular men are required to be reproduced; second, when the sitter, from a nervous disposition, is unable to sit the length of time requisite for a large picture, even were he willing to have such done; third, the

ability to produce the beauty and truth of the card five or six diameters; fourth, the reduction of large pictures to card size, and the great fact of being able to work such with very moderate light, all conspire to render this mode an exceedingly attractive one to the photographer, especially as the humblest operator has the means necessary within his reach.

SUBSTITUTES FOR ALBUMEN FOR POSITIVE PRINTING.

BY H. COOPER.*

THE finding of a substitute for albumen, for positive printing, has for a long time, more or less, claimed the attention of photographers, but I do not think that sufficient perseverance has been shown in the pursuit.

Many, I dare say, have tried an experiment or two, met with no good result, and fallen back upon albumen, leaving the trouble of finding a substitute to others possessed of more patience than themselves.

Only those who have gone on with their experiments can know the difficulties that spring up at every point. They are such that it requires many a glance at the golden end in view to keep the enthusiast from giving up in despair.

The subject of printing has at no time received the attention it deserves. Negatives can now be produced nearly, if not perfect; and it seems to me very strange that more care has not been shown in that process, by which their beauties are exhibited to the world.

As has been recently remarked, every photographer ought to produce the best result, to have the printing of his negatives under his own supervision.

But yet, when perfect prints are produced, the chances are that they are not permanent, and in a few years, or even months, their beauties begin to fade; so that, if it is the portrait of a handsome young lady, the likeness keeps pace with the original. It is a most essential point that photographs should be as permanent as engravings.

Photography is a great blessing; for by its means we may possess faithful records of places and events of the greatest national or private interest, and of the features of those far distant, or who have passed away from among us to that "bourne from whence no traveller returns."

But what is more grievous than to see the cherished likeness of a lost one gradually fading away, when we had hoped to hand those loved features down to generations yet to come.

There are some remarks of Washington Irving's on the introduction of the printing press, which apply with such force to photography, that I am sure you will pardon me for quoting them in a paper which professes to dwell upon processes and formulæ. He says:—

"The recent invention of the art of printing enabled men to communicate rapidly, and extensively, their ideas and discoveries.

"It brought forth learning from libraries and convents, and brought it familiarly to the reading desk of the student. Volumes of information, which had before existed only in costly manuscripts, carefully treasured up and kept out of the reach of the indigent scholar and obscure artist, were now in every hand.

"There was, henceforth, to be no retrogression in knowledge, nor any pause in its career.

"Every step in advance was immediately, and simultaneously, and widely promulgated; recorded in a thousand forms, and fixed for ever. There could never again be a dark age; nations might shut their eyes to the light and sit in wilful darkness, but they could not trample it out; it would still shine on, dispensed to happier parts of the world by the diffusive powers of the press."

In what a greater degree does not photography accomplish all these blessings!

I have made the foregoing remarks to impress upon you the importance of the subject, "The improvement of formulæ for photographic printing."

We *must* make our prints more permanent; and as it is exceedingly dangerous to employ albumen for printing processes, I, as you are aware, am a great advocate for its removal altogether from our formulæ.

I will briefly call your attention to the only advantages possessed by albumen. It gives great fineness of definition combined with a high degree of transparency, and depth in the shadows (which last, allow me to observe, is not always according to nature. I think I shall be supported in this idea by many).

These two good qualities are set against a long array of serious defects.

1st. The trouble and vexations failures in manipulation.

2nd. The great uncertainty of the result to be obtained.

Two sheets of albumenized paper very seldom being alike.

3rd. Its proneness to mealiness, and what I term *scarlet fever*, viz., large patches being left unacted upon by the toning bath. This is really a species of mealiness.

4th. Its great liability to become yellow by sulphurization, and thereby cause fading of the image.

5th. Its great gloss of surface, which is very inartistic.

There are many other faults to be found with poor albumen which I need not enumerate.

I shall now make a few remarks on the processes that appear to me to stand any chance of beating albumen out of the field.

The processes in question are, the resinized paper, paper prepared with india-rubber, and the new enamel paper introduced by M. Schering or Herr Liesegang, or by both these gentlemen.

On the subject of resinized paper I have not much to say, as I have made no alteration in the formula, except in the bath, which I now use of the strength of at least 100 grains to the ounce (more commonly 120), and I only float the paper from two to three minutes.

The bath should also contain 5 or 10 per cent. of alcohol, as I recommended in the first instance, or sometimes the paper will be found to repel the solution, causing a most disastrous effect.

(Mr. Cooper here exhibited a piece of paper that Mr. Simpson had received from a correspondent, in which one half was quite insensitive to light, and it appeared as if a solution of nitrate of silver had been carelessly brushed over without forming any chloride in parts.)

The only other point is to wash the prints finally in boiling water.

From the india-rubber paper I expected much better results than I have as yet obtained.

It decidedly gives cleaner lights and as good shadows as resinized paper. The following is the *modus operandi*:—Procure some pure india-rubber or gutta-percha, that sold in thin sheets is the best; dissolve it in a little chloroform, and add it to benzole in the proportion to make a solution of from two to three grains to the ounce. Shake it well, and immerse the bottle containing it in hot water till the solution is bright and free from muddiness.

Allow it to settle for some time to prevent white spots from being visible on the finished prints.

To prepare the paper, pour some of the solution into an even bottomed dish and immerse the paper in the way I described for resinizing paper.

The draining is the most important part of the process, and where a failure is most likely to occur: the paper must be so hung that one corner is lower than the other, and just before it ceases to drip reverse the position of the sheet, so that the solution may drain from the other bottom corner.

The difficulty is to get a suitable sample of benzole, as it is generally very liable to run into greasy streaks. If it has originally the least tendency this way it will only be increased by the addition of the india-rubber or gutta-percha. When the paper is thoroughly dry it may be floated on a

* Read at a meeting of the South London Photographic Society, April 9th, 1863.

solution of any of the chlorides of from 5 to 10 grains to the ounce.

A little Iceland moss may be added to the salting solution with advantage.

Float three minutes on a silver bath of 60 grains, slightly acid. Or a combination of the nitrates of silver and ammonia may be used, formed as follows:—Make a solution of ammonia-nitrate of silver, 100 grains to the ounce, and add nitric acid till the solution is neutral or faintly acid.

By the bye, plain ammonia-nitrate of silver answers very well for this paper.

The toning, fixing, and washing is performed as usual.

We now come to the consideration of the enamelled paper. Of this I have great hopes, and I think I shall soon be able to employ it successfully for cartes and the finest work.

I have not yet made any experiments with it, as I only had a piece of the size of a carte de visite for which I was indebted to Mr. Simpson.

I have since received some from Glasgow, so I trust by our next meeting to have some perfect prints on it to show you.

As the piece of paper I received was albumenized, of course, for my purpose, it was necessary to remove the albumen; I accomplished this by floating on repeated changes of distilled water (the object of my using distilled in preference to common water, you will perceive presently), gently dabbing the surface with a clean sponge. To make sure that I had entirely got rid of the albumen, I floated a small piece of the paper on the nitrate bath (I beg your pardon, *nitrate of silver bath* I should have said). I then exposed it to strong sun-light for the whole of a day, when not the least change took place in the tint except at the edges, where the silver solution had come in contact with the unprotected paper. This, also, proves that the enamel is unacted upon by the nitrate of silver. If I had used common water, a slight difference might have been made in the result.

This was, to me, a most satisfactory experiment. I have brought a piece of the paper from which the albumen has been removed; you will perceive that the surface is very nice, although it has a slightly bronzed appearance.

To salt the paper, I floated two minutes on a 7-grain solution of pure chloride of sodium, and then, when dry, on the 100-grain silver bath.

One advantage is, that the paper does not cockle in dipping. The piece I tried printed very red in the frame, but toned up beautifully to a splendid purple; upon fixing, the print lost considerably in tone, but not in strength; but, when dried, it was very much too blue.

I must try and procure some of the paper unalbumenized, and then I can set to work in a systematic manner.

I forgot to mention, that the enamel is insoluble in hot and cold water, and alcohol.

It is also unacted upon by nitric, hydrochloric, and acetic acids diluted with their volume of water. I have tried many experiments to *make* an enamelled paper, but have not, as yet, been successful.

This paper is necessarily very cursory, as through severe cold I have been prevented from carrying out a great number of experiments which I have in hand. In fact, I was rather inclined to postpone my promised communication till the next meeting, as I thought we should have plenty for the evening; but as Mr. Harmer was prevented from fulfilling his intentions, I have done the best I can to open the way for a discussion on this most important subject.

A WORD ABOUT TONING.

BY PROF. C. F. HIMES.*

A WORD on toning: I always have copper in my toning bath, because I use scraps and ends of gold in making my chloride of gold, which *invariably* have copper in them.

* *Amateur Photographic Print.*

My bath seems almost exhaustless in its toning power. It is now more than two months old, has been used at least ten times, and works as rapidly and well as ever.

When I stop toning, I pour it into a bottle, add enough hydrochloric acid to give it an acid reaction, and let it stand. When I wish to use it again, pour it into a tray and add solution proto. carb., soda, until its addition causes no more flocculent precipitate (sometimes this bath is almost *mushy*), then put in the prints. They tone in from one to five minutes, and change very little in the hypo. I also put in a pinch of hypochlorite of lime occasionally, never any salt, as I wash my prints in salt water, from which I transfer them to the toning bath; and the repeated acidifications and neutralizations give a large supply of chloride of sodium. My *stock* solution of chloride of gold is quite acid, as I never evaporate the solution to dryness, nor do I do anything in the way of neutralizing until it is used, as it keeps much better acid.

I think if there is any virtue in *brass*, I get it in my way of operations, and I must say that since I have been using this coppery gold solution, it holds out much better than before.

EDEN'S PATENT MICROSCOPIC CAMERA.

A VERY ingeniously constructed instrument of this character has recently been patented by Mr. A. F. Eden, of Crown Court, Threadneedle Street, the inventor and maker. It is made to serve a variety of purposes, and can be used either for the production of direct miniature portraits suitable for mounting in lockets; for taking reduced copies of photographic pictures to be examined afterwards by the aid of an ordinary microscope; or may be employed inversely for the production of magnified representations of microscopic objects. The instrument may be described as consisting of a photographic camera adapted to the tube or body of an ordinary microscope, and, although the combination serves the purposes already enumerated, the two portions may be disconnected, and each used separately: thus, to the mahogany camera may be adapted a landscape lens of about sixteen inches focus, when it becomes suitable for copying, and for taking small views of any size not exceeding six inches square; likewise the optical portion of the instrument may be mounted on a brass stand, and requires merely an eyepiece to constitute an efficient compound microscope.

The manner of using the instrument may be briefly described:—Supposing it be required for taking a micro-photograph or reduction from an ordinary negative, the latter is supported in the position occupied by the ground glass or dark slide in a camera of the usual construction. This end of the instrument is provided with a large plane reflector attached by a hinge, and capable of adjustment to any angle which may be required to direct the rays of the sun or diffused daylight through the negative and axis of the camera; by means of the microscope object glass in front of the camera, a sharply defined image is depicted upon the screen of a little dark box placed a short distance beyond. The lens may be adjusted and focussed by the aid of a rack-work and pliuon movement; and when the optical perfection of the image is arrived at, the scratched glass is exchanged for the sensitized plate, in this instance represented by a single drop of collodion upon a glass slide of standard dimensions, one by three inches; the exposure will not usually exceed ten seconds in bright daylight, and the development occupies but a single moment, since it is advisable to guard against too great intensity in the minute photographic reproduction, and in order that the speck of reduced silver on the glass may exhibit, under assisted vision, its proper gradation of light and shade. The beauty of the result, and the rapidity with which the whole process is executed, will possess a charm for those whose leisure moments are few, and whose laboratory facilities are of a limited character.

On the other hand, by placing in the little dark box a microscopic object mounted on a glass slide, and removing the cap or stopper which prevents the access of daylight, an enlarged and well-defined image will appear upon the ground glass at the larger end of the camera; having focussed in the same manner as before, this image now presents itself ready to be photographed on merely holding the camera directly

pointed to the sun, or reflecting its rays from the small concave mirror placed at this extremity of the instrument. And, further, by removing altogether the larger mirror, the apparatus will be suitable for taking miniature portraits of sizes varying from that of a grain of mustard seed to such as would be mounted in a small locket. The one-inch lens is that preferred for general use, but a lower power is also provided; both of these object glasses have their photographic and optical foci coincident, no allowance need, therefore, be made in the adjustment of the sensitive plate; and the fact that Mr. Eden was for some years a pupil of Mr. Andrew Pritchard is so far a guarantee for the perfection of the optical part of the microscopic camera.

COLLODION: WET OR DRY.

BY M. L'ABBE DESPRATZ.*

THE mode of developing we have previously described appears, we must admit, to complicate operations: it differs a little from the method usually followed; but as it is based upon oft repeated operations, and as it tends to yield constantly identical results, we have thought it would be useful to make it known with some details. We recur then, for a moment, to speak of pyrogallic acid; for although it is possible to obtain with this agent an excellent development in most cases, that is, when we moderate the action of pyrogallic acid by acetic acid, we do not hesitate to affirm that by proceeding as we have indicated for sulphate of iron, the results will be obtained with greater regularity and facility, when we substitute the action of acetic acid for that of citric or tartaric acid.

Some preliminary considerations must not be neglected. Pyrogallic acid, as is well known, is never employed without the previous addition of another acid. Observation has in fact shown that pyrogallic acid alone, and without the association of another acid, is so sudden in its action, that a complete decomposition of the nitrate of silver occurs instantaneously upon first contact, and that, from this moment, the pyrogallic acid seems to lose its continuing power for developing the image. The addition of an acid always retards its action. Hitherto we have had recourse principally to the vegetable acids, acetic, citric, and tartaric. If on principle we make use of the first, and if we still use it to the exclusion of the others, it is doubtless for this specious reason, that its physical constitution is more in harmony with the collodion film, its diffusion upon this film being effected with the greatest facility. Citric, tartaric, and many other acids beside, doubtless, also possess the property of moderating the action of pyrogallic acid; but viewing their physical constitution, their action, although chemically the same as that of acetic acid, can be exercised under the same conditions only with much more difficulty. The special conditions demanded by citric and tartaric acids are the same as those we have indicated for sulphate of iron, and are almost wholly applicable to them.

In following our researches in this direction, we do not confine ourselves simply to regulating the action of the moderating acid upon the silver bath; we also think that it will be interesting to know whether in securing the good development of the picture, the moderating acids do not modify its tone, and also if the image itself will be accelerated or retarded in its appearance. And thus experience has taught us that in a physical point of view, and especially in the chemical, the choice of acids added to the pyrogallic is not a matter of indifference.

What first strikes attention in the chemical point of view is that the different acids associated with the pyrogallic have evidently a peculiar action. The tint of the picture obtained is not the same with the one as with the others; besides, the acceleration appears to be variable. Finally, if they can contribute to the obtaining of a greater or lesser delicacy, they oppose more or less the tendency to *fogging*. Under these two relations, the advantage seems to be attributable to citric and tartaric acids; to the first especially, which gives

blacks of a peculiar aspect, blue in some measure and of very great transparency in the half-tones; while tartaric acid will give reddish blacks comparable with those of a positive in chloride of silver. With these two acids the picture develops slowly. It is one or two minutes before the darkest parts begin to show themselves, but as soon as they are well out, the entire picture appears with admirable regularity, and with a harmony of tone that leaves nothing to be desired. This slowness in the appearance of the image leads to the supposition, that the reducing faculty of the pyrogallic acid is diminished; but we believe that it is merely slackened. It is, however, not impossible that there is a real diminution, and starting from the fact of a special and coercive action of one acid, we can, in the hope of another action in the contrary direction, make use of some other acid. An action of this kind seems to be the property of formic acid, for example, but we have had no facilities for proving it in our experiments. Whatever it be, there are very interesting studies on this point to be pursued: and it is to be regretted that, hitherto, they have been almost exclusively limited to the employment of pyrogallic acid moderated by acetic acid.

Our studies have, however, not been limited to acetic acid. What we are about to say of citric and tartaric acids, has determined us to seek the means of deriving every advantage from them they possess. In our experiments both have been submitted to similar treatment, and both have comporting themselves alike, and the results obtained, variable with the nature of the acid, have presented themselves in the same degree. Both, therefore, require the same manipulation. As with sulphate of iron, a new sensitizing bath offers, in use, less obstacle to a regular and harmonious development; but as we have said, this is not ordinarily the case; almost always, if not always, sensitizing is made with an old bath, or more frequently, with one made old by artificial means, by the addition of iodides soluble in ether and alcohol, the alcoholic tincture of iodine, or even with a weak solution of nitrate of lead; preparations, more or less complex, and most certainly preferable to a new bath simply prepared with nitrate of silver.

(To be continued.)

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held in the City of London College, on the evening of Thursday, April 9th; Mr. SEBASTIAN DAVIS in the chair.

The minutes of a previous meeting having been read and confirmed, the following gentlemen were elected members of the Society: Messrs. J. W. Osborne, Henry Cooper, jun., and William Cobb.

Mr. MARTIN exhibited some very fine crystals of the double sulphate of iron and ammonia prepared by Messrs. Horne and Thornthwaite, and also some negatives developed by its aid, by Mr. T. R. Mills. Some conversation on the subject ensued.

Mr. G. WHARTON SIMPSON exhibited some prints by Mr. Pouncy's new process, in which the paper was prepared with printing ink and a sensitive salt, exposed under a negative, and cleared by immersion in a solvent of the printing ink, the result being a photograph in printing ink, presenting the due gradation of half-tone. The prints were examined with great interest. As analogous in character in some respects, Mr. Simpson also showed some photolithographs by Asser's process, executed by Messrs. Simonau and Toovey, of Brussels. These were also considered very successful, especially in the half-tone. He also exhibited some specimens on enamel paper he had received from Herr Liesegang, which were much admired. He further called attention, as not less connected than the pictures he had already shown with the subject of the evening, printing, to Mr. Penny's specimens of the effect of fuming albumenized paper, illustrating its value, and to some specimens of his own in which he had failed to secure any advantage by this process.

Mr. COLE presented to the Society some card portraits taken in Rome, of various eminent men; which were examined with much interest.

* Continued from p. 101.

Mr. SYDNEY SMYTH exhibited some very fine enlarged prints by the solar camera, which he explained were produced by development on Hollingsworth's drawing paper, prepared with a bromide and a chloride. The sheets were washed in troughs, and the paper in question was the only kind which, in such large sheets, would bear washing without tearing.

Mr. COOPER showed some pleasing specimens, amongst which was a charmingly lighted copy of a bust of the Princess Alexandra, the print being about half the size of the bust, produced by Dallmeyer's No. 1 Triple lens.

The CHAIRMAN announced that Mr. Harmer was unable to read his promised paper on "Double Printing," but Mr. Cooper would now proceed to read his paper prior to resuming the discussion on Mr. Price's paper.

Mr. COOPER then read a paper "On Substitutes for Albumen in Printing," (see p. 186).

A conversation then ensued upon the enamel paper, a sample of which, with the albumen coating removed, but leaving an enamel surface, he produced, and also a print upon it, salted after removing the albumen. Various opinions as to the constitution of the enamel were expressed. In answer to the suggestion that lead was used in producing a similar surface,

Mr. SIMPSON said that he thought that lead was not employed in this case, as he had tested it with sulphide of ammonium, which did not produce any blackening. He was disposed to think that probably sulphate of baryta was used.

Mr. J. W. OSBORNE thought it very likely that either the sulphite or carbonate of baryta was used, as they were both very suitable substances. It was probably mixed with dextrine or some paste, supplying no sulphur compound. It was a matter of surprise, however, that the enamel remained perfectly intact, after the treatment necessary in removing the albumen.

The CHAIRMAN suggested that a varnish of some kind not soluble in water was the vehicle of applying the enamel to paper.

A Member suggested that it might be soluble glass.

Mr. COOPER thought not, as he had tried that himself. It gave a beautiful surface to the paper, but quite dead, and it became decomposed on coming in contact with the nitrate of silver.

After a desultory conversation, in which Mr. Cooper referred to the fact that the enamel remained unaffected by nitric, sulphuric, or hydrochloric acids,

Mr. MARTIN said that this fact inclined him to the opinion, already suggested, that soluble glass had been used in obtaining the enamelled surface. The silicate solution was probably applied to the surface, which was then submitted to the vapour of carbonic acid gas, which would precipitate the silicate on the paper.

Mr. COOPER's experiments with silicates inclined him to think not, as the solution at once penetrated the paper and left a dead surface, whereas this enamel was entirely on the surface.

After some further conversation, Mr. HARMAN stated that he had found in using resinized paper that a floating of three-quarters of a minute gave more brilliant prints than a longer application.

Mr. S. SMYTH said, in reply to the Chairman, that he used resinized paper for the solar camera and liked the result; the print was more on the surface and more brilliant than with plain paper.

A desultory conversation followed on the relative value of Hollingsworth and Turner's papers, on tinting photographs on resinized paper, on printing on tinted papers, on dyeing or tinting the prints subsequent to printing, &c.

After a vote of thanks to Mr. Cooper, the debate on Mr. Price's paper was resumed.

Mr. J. W. OSBORNE had not had the good fortune to be present when Mr. Price read his paper. He had read his paper with great interest in the pages of the NEWS, and as it was a subject in which he felt interested he had followed it up with some experiments, in the course of which he had found some inaccuracies in Mr. Price's statements. He referred to that part of his paper wherein he stated that M. Gaudin was in error in stating that a hot iron applied to paper which had been rendered damp would coagulate the albumen. He would read the passage from the PHOTOGRAPHIC NEWS (see p. 127 of our present volume). On reading this and remembering his own experience he thought M. Gaudin was right, and his experiments proved that this was so. A very small amount of moisture was sufficient to permit the coagulation of albumen. He had

tried various ways of moistening the paper, and used it with different degrees of moisture. Amongst other methods he might mention he had placed the albumenized paper between sheets of damp paper and allowed it to get just so moist that it was no longer crisp. Strips of this he passed over a heated Italian iron, the plain side in contact, and the result was coagulation. He was not prepared to say that this could be done easily with large sheets. It required, moreover, great care and attention to manage it properly; too great a heat would scorch the paper, and too little would not produce coagulation; and it was more-over possible to scorch the paper without causing coagulation. He had himself been surprised to find that on ironing a sheet of damped albumenized paper, with a sheet of paper over it, coagulation followed. Mr. Price had shown a great readiness to admit any error or mistake he had made, and he felt sure he would be glad to have this error corrected, arising from his too hastily having assumed that coagulation could not be effected in the manner proposed.

Mr. PRICE said he had tried the experiment and no coagulation whatever was the result. He put the paper in an extremely damp place and then ironed as M. Gaudin had directed, but without producing any coagulation.

Mr. OSBORNE was not surprised. It was very difficult to succeed and very easy to fail. He would probably have found that an Italian iron would have answered best as giving the most control over the heat.

Mr. PRICE had used a box iron. He had also had some paper submitted to the steam passing from a safety valve, which, however, produced no coagulation.

Mr. OSBORNE said it was possible that it was equivalent to dry heat, which would not, of course, cause coagulation. In his operations for coagulating the albumen on the photolithographic transfer he had less difficulty in effecting it by floating as the gelatine present held the moisture and prevented evaporation. He found it impossible to coagulate the albumen by floating on an open vessel of boiling water, as the evaporation carried off the moisture from the paper too rapidly; but if the vessel were covered for even a few seconds, coagulation was produced. The operation was, though difficult, still possible; the point to be settled was whether paper so treated could be produced as a commercial article, and if so, whether it possessed any special advantage.

Mr. PRICE was not sure that even if effected by steam, a portion of the chlorides might not be removed by the operation.

Mr. OSBORNE thought it quite possible; indeed one of the samples upon which he had experimented, when printed upon, gave a very unsatisfactory result, and he thought the chlorides had been washed out.

Mr. SIMPSON believed that any steam at a temperature less than 214° or 216° was too moist and would be likely to deprive the paper of a portion of the chlorides, even if it effected coagulation.

Mr. PRICE had many experiments, and had tried steam, because Mr. Simpson had shown him some paper in which the albumen was rendered insoluble by steam. The sheets submitted to the steam from a safety valve, had been moist, for they all stuck together. He had not succeeded in coagulating the albumen in any of his experiments. There was, evidently, great uncertainty as to success.

Mr. OSBORNE said that was doubtless the case.

After some further conversation,

The CHAIRMAN recurred to Mr. Price's objection to the term "coagulation," as produced by metallic salts. He thought the objection not based on certain grounds, as there was no proof that albumen was not coagulated independently of any compound which was formed.

Mr. PRICE maintained that it was a new compound which was formed by the combination, and that it was a misnomer to call it coagulated albumen.

Mr. OSBORNE said there was no proof of chemical combination being formed, substances always combined chemically in definite proportions, and we had no evidence of such combination between albumen and silver.

The CHAIRMAN said it might be an entanglement of nitrate of silver with coagulated albumen, and the term coagulation might be strictly correct in the sense used by authorities.

Mr. SIMPSON thought in such discussions it was most important to define terms, and he thought there could be little doubt that the term coagulate, according to either philological or chemical authorities, meant the changing of a substance from a fluid to a solid state. The coagulation of albumen was de-

scribed by chemists as an isomeric change, and it was certainly not such a change which was produced by nitrate of silver. He believed that chemical authorities had always regarded the insoluble substance produced by the action of strong acids or metallic salts upon albumen as direct compounds between the bodies. To the photographer the simplest evidence of the formation of a combination was the fact that the compound blackened by light. Nitrate of silver alone and albumen alone were unaffected by light; whilst the compound readily blackened. It would scarcely be alleged that any mechanical entanglement of the two or mere intimate contact, without a chemical combination, would enable light to bring about the chemical change involved in the blackening. The fact that the proportions in which these substances combined was not well known was no proof that a definite combination did not take place. If a new compound then were formed, the term "coagulated albumen" did not properly define it.

A somewhat lengthy conversation on the subject followed, in which the Chairman and Messrs. Price and Osborne took part, after which the proceedings terminated.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, April 15th, 1863.

M. Sabattier-Blot exhibited to our Society an apparatus for operating in the open air without the aid of a tent. It consists of two superimposed boxes, the upper box is the ordinary camera, only its position is reversed, the objective occupying the place where the ground glass is usually found. On the front is a board, which opens upon hinges. Inside this board two brackets are adapted to slides which hold a piece of wood to which is adapted the crutch in the form of a T, upon which the plate is fixed by means of little hooks. This crutch or hook, placed, vertically, is moved by means of a button placed outside, which permits it to be raised or lowered into the several baths.

The groove which admits the passage of the button is formed by means of a piece of caoutchouc or oil-cloth.

The hook which supports the plate is very easily removed by turning a little screw, which permits of the hook being immediately cleaned.

The lower box contains another box lined with gutta-percha, in which are placed two, three, or four glass baths, which by means of a little rack are placed successively under the hook. This operation is performed so exactly, that the hook and the plate it sustains can enter easily, without friction, into a bath of 6 millimetres ($\frac{1}{4}$ of an inch) in thickness. When ready to operate, the hook is removed, and the focus obtained on the ground glass, the prop is then placed; the plate is covered with collodion, and then immersed in the nitrate bath. After it has remained sufficiently long in the bath, the plate is removed and drained for a few seconds, and then exposed. As soon as the picture is taken, the developing bath is brought to its place by means of the rack, and the plate promptly immersed in it. It now only remains to fix and wash it, which can be done in the box if desired, or outside, as many operators do.

The negatives thus obtained are generally weak, but very delicate, and very well adapted for reproducing and enlarging. If it is desired to strengthen them immediately, there is a very simple way of doing it; we can make use of a little box of gutta-percha, into which we let fall the plate and the hook. This box has both sides furnished with windows of yellow glass, through which we can see when the operation is concluded; by this means we strengthen the negatives with as much facility as in the dark room.

The advantages claimed for this apparatus by the inventor are, that the operations are very easily performed, without slides, dark room, or soiling the fingers.

In one of the photographic ateliers of Berlin, a curious phenomenon lately exhibited itself. When alcohol varnish

was poured upon the negatives, dried and warmed, the collodion broke up and came off with the excess of varnish, and only the intense blacks remained on the plate. At first the phenomenon occurred with but a few plates, but it soon began to occur very frequently, so that at last almost every negative was damaged during the process of varnishing. Operators were compelled to use gum arabic instead of varnish, so as not to lose all the fruits of their labour.

When this fact was communicated to M. Vogel, he concluded that the varnish contained some acid. To make sure he added twenty drops of liquid ammonia to two hundred centimètres (seven ounces) of varnish; a flocculent precipitate appeared, which was entirely redissolved upon warming and shaking the bottle.

The varnish prepared in this way no longer exhibited the phenomenon in question. Although we may conclude from this experiment that the acid contained in the varnish was the cause of the destruction of the collodion, testing with litmus paper showed very little acid in many samples of varnish. It may therefore be presumed that there are other causes to be discovered.

The film of collodion does not become insoluble in drying. If we pour upon it some alcohol mixed with a little ether, the collodion breaks up in the same manner as with the varnish. It is therefore probable that the varnish (an alcoholic solution of resin) *dissolves* the collodion. This dissolving will take place if the collodion be very soluble, or if the alcohol of the varnish be very strong; it is easy to remedy this inconvenience by adding a little water to the varnish, say twenty drops to seven ounces of varnish, heated in a retort, a white precipitate is formed, as with the ammonia, which dissolves rapidly upon being shaken.

The varnish, thus treated, no longer acts injuriously upon the collodion film, and leaves nothing to be desired.

The analogous action of ammonia is due only to the water it contains. The neutralization of the acid seems to play an insignificant part.

THE MOTION OF CAMPHOR TOWARDS THE LIGHT.

SIR, my attention has been called to a statement by Dr. Draper in your last number (p. 178), abridged from the *American Journal of Photography*, to the effect that he, Dr. Draper, is the author of a theory of the motion of camphor, &c., towards the light, similar to that which I submitted to the British Association at Cambridge, in October last, an account of which is given in the *Philosophical Magazine* for November last, and in greater detail in a small volume recently published by me, entitled "Experimental Essays."

Dr. Draper has already made a similar statement in the *Philosophical Magazine* for January last, and my reply to him is contained in the *Philosophical Magazine* for February. As many of your readers may not have seen my reply, perhaps you will allow me to re-state it in your next number, with a few additional particulars.

In a dispute of this kind more assertion should be carefully excluded, and the only evidence adduced should be documentary printed and published statements, with the dates open to all the world.

Now I cannot help remarking that Dr. Draper deals in mere assertion when he states, "I finally came to the conclusion that the old theory was incorrect; that the crystallization was not caused by the light, but by the heat. The side of the vessel nearest the sky becomes the coldest, and the camphor crystallized upon it simply by virtue of its being a cold surface. Any thing placed before it to obstruct radiation will prevent the formation of the crystals."

All this, so clearly stated after my own labours have been published, sounds exactly like my own language, and is indeed my own theory. Dr. Draper claims it, but where are the published proofs of his claims? The only attempt at proofs given by him in his letter to the *Philosophical Magazine* in January last, is a question put by him in 1840 in the same magazine, whether the side of the jar next the sun may not, after all, be the colder? This was a passing idea, and he proceeded to test it by the light of an experiment which he describes in his quarto volume, "On the Forces which produce the Organisation of Plants," published

at New York in 1844. At page 124 of the appendix he says, "It might be suggested that when a vessel is exposed to the sun, that part of the glass which is nearest to him may actually be the *coldest*; such an opinion, it is evident, rests on no sufficient grounds." He then describes the experiment, in which a differential thermometer, enclosed in a jar and exposed to the sun, proved that the side of the jar nearest to the sun was the warmer, and adds, "Hence we know that in all cases where crystals of camphor, dew of water, &c., are deposited on the side next the sun, they are so deposited in opposition to an energetic force which tends to remove them."

This is pretty strong evidence that Dr. Draper's theory is very different from mine.

A few more statements from this volume will show that Dr. Draper tried at least six theories to explain the phenomena in question, and failed in all.

At p. 120, he says:—"The sun's rays have the power of causing vapours to pass to the perihelion side of vessels in which they are confined, but, as it would appear, not at all seasons of the year." He then describes a case in which, during December, January, and part of February, "a deposit was uniformly made towards the sun; during the months of March, April, and part of May next following, although every part of the arrangement remained to all appearance the same, yet the camphor was deposited on the side furthest from the sun. *It does not appear that any immediate cause can be assigned for this waywardness.*"

Could Dr. Draper have put forward such a statement as this in 1844, if he had had the slightest idea of the true theory of the motion of camphor towards the light?

Again, p. 122, when a circular plate of glass was put into a glass receiver above the camphor, no deposit was made on the plate. Dr. Draper says, "It was not without surprise I observed that, however long the plate was continued in the beams of light, no crystallization would ensue." Cases of this kind are perfectly explicable on my theory, and, indeed, I give several such.

Commenting on such a case, Dr. Draper says that "to reduction of temperature we cannot look for an explanation." I prove that reduction of temperature is the only means of explanation.

Again, at p. 122, Dr. Draper says, "Why does this condensation take place on the hottest surface, the side nearest to the plate? *We cannot admit that the rays of heat have any active part in bringing about the phenomenon.* On the other hand, they ought rather to exert a contrary effect, antagonizing the powers that solicit the camphor crystals to form, and driving them to the coldest surface. We are therefore reduced to the supposition that, when the light of the sun impinges on a surface of glass, it places that surface in such a condition that it exerts a pressure on the adjacent medium, immediately followed by a condensation of that medium."

I have no idea what this means; but I would ask how it is possible Dr. Draper could sanction such statements in 1844, if, as he says, he had adopted my theory in 1840?

At page 124 he says that "light which has suffered reflection at certain angles seems to have undergone a remarkable modification, being no longer able to put the glass into such a condition that it can cause motion towards the sun." Does this look like settled theory?

Nor is the action of metal screens and tinfoil rings in preventing a deposit at all explained. At page 126 it is stated that "the ring exerts a kind of protecting action," &c. Again, "This action of a ring formed of good conducting materials might be supposed to arise either from its adding something to the surface of the glass, or taking something away from the glass with which it is in contact; or it might be imputed to some change impressed on the ray of light, &c."

The electrical theory is started at page 127, in which it is supposed that a glass exposed to the sun's rays becomes electrified in an opposite state to that of the camphor, and consequently attracts it; but that a ring or screen of tin-foil prevents such action, &c., &c. At page 128 it is stated that, if the inner surface of the glass receiver be rubbed with a glass rod, the camphor will deposit itself on the lines traced by the rod. Although the explanation of this fact is perfectly easy, yet Dr. Draper compares the result with Lichtenberg's electrical figures, and proceeds to ask, "Are we to refer this singular action to the rays of light, to the rays of heat, or to the chemical rays?" He then proceeds to pass the light through solutions of ammonio-sulphate of copper, bichromate of potash, &c., and obtains what he calls "aphelion camphor deposits." He says, "It does not necessarily follow from the phenomena that any pecu-

liar class of rays is emitted by the sun which bring about this action; but if there are such, it is a question of interest to find what is the reason that good conductors of electricity render their action nugatory."

Now is it conceivable that Dr. Draper could have published such statements as these in 1844 if he had had the faintest idea of the true theory? Or is it conceivable that so industrious and ingenious an experimentalist would not have devised experiments to test his theory had it been the same as mine, and which he now admits to be a sufficient one? I have looked in vain for any indication of such an attempt. Instead of any settled theory, I find a large number of theories, and a large number of experiments, but nothing is settled. In fact, Dr. Draper makes a lottery of a number of theories, and draws out blanks so far as the explanation of the phenomena in question is concerned; and when, twenty years later, another inquirer draws a prize, he claims it as having come from his original lottery.

If Dr. Draper advanced the true theory in 1840, it made no impression on himself or on others. No scientific writer, to my knowledge, either in America or Europe (and I have searched far and wide for the purpose), has ever had a doubt that the camphor deposits are produced by the action of light. Nor do I now see any cause to alter one of the conclusions of my paper, viz., that the result of Dr. Draper's labours was "to multiply phenomena, and to leave the theory as it was."

The above statement has already been given in the *Philosophical Magazine* for February last. Should it be necessary, I have other proofs that so late as 1860 Dr. Draper had no idea of the true theory of motion of camphor towards the light.—I remain, &c.,

C. TOMLINSON.

King's College, London, April 13, 1863.

Photographic Notes and Queries.

SATURDAY HALF-HOLIDAY FOR PHOTOGRAPHERS.

SIR,—It was hoped good things would come of the circular issued by Messrs. Ackland and Godbold, soliciting signatures of employers photographic to a form affirming their willingness to concede the Saturday half-holiday to operators, &c., from the 7th of March.

The day certainly appeared an appropriate one for such a change to date from, but it came and brought no change.

Hence my reason for troubling you with the following suggestions:—

That Messrs. Ackland and Godbold constitute themselves bankers for the receipt of "hard cash" to be used to advance the cause of health in Health *v.* Cyanide and others; and that the Early Closing Association's boards would be a good medium to advise the public of our wishes, and how to gratify them.

I would also hint, that the majority of west-end customers on Saturday afternoons are drapers' assistants, who no sooner rid themselves of the last counter-feat than they go in quest of another, and injudiciously bother the photographer with the study of the drapery line in all its beauty.

The aristocrats, by deed and word, some time ago, gave in their adhesion to the half-holiday movement.

I remain, sir, your obedient servant,

TANTALUS.

DIRECT IMAGE ON TANNIN PLATES, &c.

SIR,—It may be perhaps interesting to some of your readers to know of an incident which occurred to me the other day when taking a view, which shows the extreme sensitiveness of the tannin process (or rather a slight modification of it) which I have for some time past used—viz., that after exposing above the usual time for a plate of that description, I found, upon opening the slide to develop the plate, a perfect view on it of the subject, with detail, &c., very well brought out without any developing, filling up an oval space of about three-quarters of the plate with an oval of light round it. That portion of the plate outside of which had as usual only an invisible image on it which was brought out by developing in the usual manner. It is possible, but I am inclined to think improbable, that the plate was not perfectly dry at the time of exposure.

Seeing a letter in your paper by Mr. Bartholomew regarding his morphine process, I find that he has omitted one most im-

portant remark, viz., how many grains of nitrate or chlorido of morphine does he use for a pint (16 ounces) of 30-grain bath solution. Perhaps you can supply this deficiency, as upon these minutiae often a process depends, and they are often forgotten by photographers in describing their processes.—Yours, &c.,

Gibraltar, March 30th, 1863.

ALEX. B. BROWN, Licut., R.A.

[From the print received we are much inclined to think that the centre of the plate had been slightly moist when exposed. Mr. Bartholomew has more than once stated that he uses one grain of muriate of morphia in eight ounces of bath solution.—Ed.]

To Correspondents.

JUSTITIA.—Your specimens exhibit an immense improvement in your lighting: the modelling in the male figure, No. 4, is very excellent indeed. We do not consider the coat at all too light for well-lighted black cloth. Regarding the increased exposure necessary, we fear we cannot help you, except by suggesting a few experiments to admit a little more light without altering the balance or proportion of light and shade. Also try a quick-acting lens, or one which will define sufficiently well with large aperture. We do not know whether the collodion you mention is quick or slow; but the chemical conditions in your pictures seem all right.

A. LEXARIC desires us to state "the failures and causes of the enclosed prints," which are reduced copies of a card portrait. If the original be good, the first failure arises from under-exposure and over-development of the reduced negative, producing a hard black and white print without detail. One of the prints is imperfectly fixed from the use of weak or old hypo, or the prints sticking together. Insoluble hyposulphite of silver has been formed in the print, which, decomposing in the light, produces the dirty brown effect.

R. G.—We do not know any one who has tried the collodion in question with the formula to which you refer; but we have heard of several who have failed with the formula.

W. C.—The enamel paper to which we referred did not, in our hands, present the drawbacks to which you refer in another sample. It did not crack if care were used; was remarkably pure and deep in the shadows, and was quite free from meanness. We have just been favoured with another sample from a correspondent in Berlin, which we hope to try shortly and report. We shall try Schering's also, when a promised sample arrives.

GEORGE LEWIS.—We should not apprehend any danger to sensitive plates placed to dry in a mahogany box, provided that the plates rest on clean blotting-paper. A coating of good varnish could not do any harm. 2. The term "good light" is very indefinite, but we should say from half a minute to a minute. A good rule for exposure with tannin plates is to give them at least six times as long as wet plates.

A. B. S. N.—In our experience, decidedly No. 2.

H. G.—Any silver in old developing solutions will be precipitated as a metallic powder, by standing. Or, if not, it may be thrown down as a chloride by adding salt.

Y. B.—We can only advise you in general terms, as it is impossible with any certainty to decide without personal examination as to the best mode of arranging the blinds. Primarily, all your pictures are considerably under-exposed and over-developed, giving simply black and white results. Lack of detail is the result of under-exposure. In the next place, your light is too much directly in front of your figure, which destroys relief and modelling. Get your light a little more from one side than the other; use a collodion containing more bromide and expose longer. The colour of your background is good; that of the curtain may possibly answer, but is scarcely what we should select.

X. Y. Z.—If the specimen sent be a fair sample of your work, we should imagine that you will have little difficulty in obtaining an engagement as operator. The amount of remuneration will necessarily depend much on circumstances. The salary of a competent operator in London varies from two guineas to five guineas a week. The posing, lighting, modelling, and printing, of your print are all good. It only fails a little in definition. The tone is slightly inky.

J. L. F.—Print deeper, and tone deeper if you wish to secure black tones. But your negative is scarcely vigorous enough for that purpose. With a weak negative use a Rive paper; with a hard negative use Saxe paper. The pose is somewhat stiff.

SOL.—The same sensitizing and toning baths which you use for albumenized paper may be used for resinized paper. Mr. Cooper recommends a strong silver bath, with the addition of a little alcohol. See his paper in the present number. 2. There is not usually any difficulty in obtaining purple tones with the bath of gold and acetate of soda; if you can get sepia or black tones, but not purple, it must arise from some peculiarity of the paper. 3. The addition of a little bromide to the collodion you name will probably aid you in securing half-tone.

W. A. S.—The exact time required for fixing is a point upon which some uncertainty prevails. We should regard 4 or 5 minutes as too short a time with a highly albumenized Rive paper. It is quite possible that 10 minutes may be sufficient, especially if in that time the purple tone, which had disappeared at the first immersion, has been restored. Imperfect fixation generally shows itself in a few hours, as the undissolved hyposulphite of silver left in the print by imperfect fixation decomposes very rapidly, producing a dirty yellow or brown.

ONE OF YOUR EDITORS.—A bromo-iodized cadmium collodion is best suited to a hot climate both for keeping qualities and excellence of general results. Develop with iron and intensify if necessary. 2. A similar collodion, but containing a somewhat less proportion of pyroxaline and iodide, is good for positives. A little of an alkaline iodide, say ammonium, is also of some advantage. For positives the free use of tincture of iodine in the

collodion is generally an advantage. See collodion formulas in our YEAR BOOK OF PHOTOGRAPHY, 3. There is no danger in taking ether or collodion a voyage through the tropics, if they are properly packed. The bottles should not be more than three quarters full so as to allow for the expansion of their contents. They should be well stoppered and tied down, and securely packed to prevent breakage.

FREDEBICK BARTON.—We are much charmed with your copies of etchings; their effect on the resinized paper is extremely pleasing. The copy of Bertalozzi's engraving is very successful and very beautiful; the peculiar tone is admirably reproduced. Your difficulty in obtaining black tones with the resinized paper is somewhat an anomaly, as any complaint of the tone which has reached us has generally been of too great a tendency to run into the black tone.

W. L.—The wind either in open air portraiture or landscape photography is a sad enemy to the photographer: we are afraid we cannot suggest any means of circumventing it. We are glad to hear of your success with the new developer. Report on your glass in our next.

EXCELSIOR.—Judging from the character of the street view, we should say the fault arises from excessive over-exposure, destroying all contrast. The mixture of the collodions in question produced a sample much more sensitive than you had been working with. Try reducing the exposure very considerably, and let us know the result. 2. A slight amount of discoloration in your bath for exciting paper will not do any harm. It is easy to remove the colour when it gets too deep, using either a little of a solution of citric acid or chloride of sodium, if you have not kaolin at hand. Do not add ammonia to a bath which has been some time in use.

J. W.—See preservative process by Mr. Blanchard in our YEAR-BOOK OF PHOTOGRAPHY for 1863, also at p. 578 of our last volume.

A. & S.—The marbled mottling on the paper sent is very like what occurs in the use of a silver bath nearly exhausted. We have seen a similar result arise when, from some cause, the surface of the paper was repellent, and had not sufficiently long floating. Perhaps the most probable cause is one which sometimes occurs when several sheets of paper have been excited without disturbing the solution, the upper stratum of which gets robbed of its silver, whilst the stronger solution, having a greater density, remains below; a very slight agitation will of course restore the balance; but under some circumstances that agitation is necessary.

S. X.—We cannot with certainty state the cause of the light spots in your print. They look like the result of contact with an acid before the hypo was entirely removed. 2. The abraded marks on the albumenized paper have certainly the appearance of having been done purposely. An albumenizer informed us that such marks were not unfrequently found on the paper before albumenizing. The dog is very good, with the exception of the slight movement of the eyes. The lady is lighted a little too directly from the front to secure sufficient contrast and modelling.

G. PAARKING.—See answer to A. M. in our last.

FAITH.—Use white blinds to regulate the amount of light from roof and left side, and white screens to get reflected light on right side. Avoid too free use of top light. See article on Glass House in our ALMANAC for this year.

TYRO TANNIN.—The use of simply bromized collodion has not been common, but it has been tried. Mr. Crookes experimented with it some years ago, and we think also Mr. Berry. It is not usually supplied by any maker; your best plan will be to get plain collodion, or make it, and add bromide of cadmium about four grains to each ounce. Major Russell has not yet entered into specific details. For development try one grain of pyrogallic acid, and from one to two grains of carbonate of ammonia in an ounce of water.

J. BERGESS.—Mr. Cooper, to whom we sent your sample of paper, has occasionally met with a similar result, where the paper has from some cause repelled the silver solution. He recommends as a safeguard the addition of a little alcohol to the silver bath. See his paper in the present number.

J. P.—Registered photographs are not required to be specially marked, and every person vending a copy, in any form of a copyright photograph, is liable for his own act, and risks incurring penalties. We can readily conceive that the subject may cause serious trouble to manufacturers sending out goods in boxes ornamented with photographs, as it may easily happen that they may unconsciously be selling pirated copies. The law does not recognize ignorance of its enactments as any justification in case the law is broken, nor does it recognize ignorance of the ownership of property as a justification in case of appropriation. A person who, therefore, appropriates a right to copy a photograph, simply because he does not know that any one has a property in it, does so at his peril. In order for any one to have a right to copy, he must first ascertain, at the cost of whatever labour or effort may be necessary, that he does not infringe the rights of others. A simple plan would be to inquire of the original photographer, or to pay the proper fee and examine, at Stationers' Hall, the Registrar's list. This may be troublesome, but it is honest and safe. We shall, probably, have more to say on the subject shortly.

W. B.—Mr. Wood will have pleasure in explaining any special point regarding his transfer process, respecting which you may desire information; if you will specify your wishes.

A. WOOD.—We shall be glad to receive and try some of the prepared paper you kindly offer. Your first letter was, as you conjecture, received too late for insertion that week.

N. JOCELYN.—Thank you for your communication and samples of paper. Both shall receive attention in our next. Several correspondents in our next.

NATURE PRINTING AND PHOTOGRAPHY.

Our readers will find on another page an interesting paper on the "New Process of Auto-Typography" read by Mr. Wallis at a recent meeting of the Society of Arts. We wish to call the attention of experimental photographers to the details of the process, and also to add one or two suggestions as to the possible combination with this process of photography, so as to produce from the photographic negative engraved plates in relief or intaglio, as described by Mr. Wallis.

Mr. Wallis's process, as will be seen, is analogous to that known as "Nature Printing," by which impressions of natural objects are obtained on metallic plates, and the down of a feather or the frond of a fern, are made to yield their forms to plates capable of being printed in the usual way. Many photographers have observed that the collodion negative presents definite relief, the deposit on the high lights often being palpably higher than the deep shadows. Mr J. W. Osborne has actually produced metallic impressions of such relief by placing upon the negative a piece of tin foil and submitting it to the pressure of a rolling press. It is true that hitherto the relief has been chiefly observed in subjects possessing strongly marked contrasts, such as copies of line engravings, &c., but it may be fairly assumed, although it may have been appreciable only in such cases, that the relief doubtless exists in absolute relation to the gradation of the negative. It is observable, moreover, in a much more marked degree in some negatives than in others, in cases for instance where a considerable amount of silver has been piled on in the process of intensifying, and also in negatives submitted to the continued action of bichloride of mercury for a few hours, in which case a considerable deposit of mercury is secured.

The question then arises, Can a negative be obtained with a deposit to produce mechanical relief in a sufficiently marked degree to be capable of yielding a printing image after the fashion described by Mr. Wallis? We think it is by no means impossible or even improbable. It is at any rate a question worthy of careful consideration, and we again recommend Mr. Wallis's paper to our experimental readers.

The methods of obtaining relief with the bichromates in combination with gelatine is already known, and it may be worth consideration, whether Mr. Wallis's method might not be found useful in connection with this process.

We learn from the interesting report of the proceedings which followed the paper, in the *Journal of the Society of Arts* that plates were actually produced during the course of the evening and printed by a copperplate press, the impressions being distributed amongst the auditory, proving at once the simplicity, rapidity, and efficiency of the process.

BROMIDES WITHOUT IODIDES IN THE TANNIN PROCESS.

SINCE our brief announcement, a few weeks ago, that Major Russell had found a considerable accession of sensitiveness in tannin plates, on using a collodion salted with a bromide alone, without any iodide, we have had many inquiries as to the best bromide for the purpose, and the proportion to be used. Some ten years ago the use of a simply bromized collodion for the wet process was in considerable favour amongst many high authorities, Sir J. F. W. Herschell, Mr. Crookes, the Abbé Laborde, Mr. Berry, and others, being amongst its warm advocates. We find, on reference, that various portions, from four grains to ten grains of bromide to the ounce of collodion, were recommended, and that the bromides of cadmium, calcium, and ammonium had their respective adherents. Some years ago we tried a series of experiments with collodion prepared with four or five grains of bromide of cadmium to each ounce of collodion, but with less satisfactory results in the wet process than were produced by a mixture of the bromide and iodide.

Major Russell, seeing our reply to a correspondent on this subject, kindly furnishes us with the following hints for the guidance of our readers:—

"DEAR SIR,—In the 'Answers to Correspondents,' I see that you recommend the trial of 4 grains of bromide to the ounce of collodion; I do not think that this will be sufficient: the formula which I find to answer best is:—

Pyroxyline (which will make a quick-setting collodion)	5 grains
Bromide cadmium	8 "
Alcohol '805	3 drachms
Ether	5 "

Excite in a 60-grain bath saturated with bromide, and keep in fifteen or twenty minutes; this will make a very creamy film. The bromide will not burst out if used in much larger proportion, but may prevent the setting of the collodion, if not of a quick-setting kind.—Yours truly,

"RUSSELL."

STRANGE DISCOVERY—PRE-DAGUERREOTYPE PHOTOGRAPHS.

A STRANGE discovery, of peculiar interest to photographers, has been the subject of conversation in scientific circles for some short time past. It is neither more nor less than the exhumation from a pile of old papers, &c., of several photographs alleged to be of a date at least half a century prior to the supposed discovery of the art. They consist of sun pictures on silver plates, much resembling the early daguerreotypes, and of paper pictures unlike any photographs of which we have at present any knowledge. We have been favoured with a sight of these sun pictures and with many interesting particulars of their history; but in deference to the wish of the gentleman who has charge of the subject, we refrain from any statement of details at present. The gentleman to

whom we refer has been for some time collecting historical and other evidence on the subject, and hopes shortly to be able to present not only a clear case establishing the production of the pictures in the eighteenth century by James Watt or his partner Mr. Bolton, but also to publish some account of the method employed. Until his case is perfect to his own satisfaction, he naturally deprecates discussion of the subject. We are promised the earliest intelligence of full and accurate details, and we refrain, therefore, from giving further particulars than have already appeared in print, the whole of which we may add may not be quite exact. The first published account of which we have any knowledge appeared in the *Birmingham Daily Post* of the 16th inst., from which we subjoin a somewhat lengthy extract. Before doing so we give a more summarised extract from last week's *Reader*, as follows:—

Photography, there is ground, it seems, for thinking, is not so recent a discovery as has hitherto been supposed. It is said that James Watt had an inkling of it, as of so many other things, seventy or eighty years ago. Among the household lumber of the family of Bolton, Watt's partner, a silvered copper-plate has turned up—now in the Patent Museum of Kensington—having on it an impression of the old premises of Watt (or Bolton) at Soho, Birmingham. The impression represents the old house as it was a long time ago, not as it now is, or has been within ordinary recollection; and those who have seen the plate have no doubt of its being, in some way, a photograph. Whether it may not be a photograph recently made from some old drawing or engraving is worth inquiring; but authorities are disposed to think it is not. Moreover, there exists traditional evidence of some sort of experiments that could now be called photographic, in which Watt, Bolton, Priestley, and others, belonging to a so-called Lunar Society about Birmingham, were engaged. An old man of ninety (recently dead or still alive), recollected, or recollects, that Watt and others used to take portraits of people in a dark room; and there is a letter extant of Sir Wm. Beechey, a portrait painter or artist of those days, begging the Lunar Society to desist from these experiments, as, were the process to succeed, it would ruin portrait-painting.

The following is from the *Birmingham Daily Post*. It is, perhaps, necessary to premise that the speculations on the subject, although interesting, are the writer's own, made without a full knowledge of all the circumstances, and must be taken *quantum valet*:—

There is an art called photography, which has hitherto not been connected with our town, excepting by its practice. In this respect, however, Birmingham is but on a level with the rest of the world; for the practice of this art is co-extensive with human vanity. We think, however, that Birmingham must now figure in the history of this beautiful art, and that, too, in a way which will probably clear up some of the dark passages in the course of photographic discovery.

A distinguished chemist in London, writing a few days ago to a friend of his in this town, says:—"The following extraordinary fact will interest and surprise you. Yesterday I was at the Patent Museum, and inspected some recent additions obtained from lumber, formerly in the possession of the Boulton family. I saw two copper plates, plated with silver by the old process. They had been carelessly kept, face to face, and are much scratched. On one is a photographic image of the old house at Soho. It has been ascertained that the house was altered at a certain date, and that the image in question is of the house *before* the alteration. This was produced by James Watt! There are also many paper photographs which were produced by J. W. Further, distinct evidence has been got to show that J. W. was engaged in photographic experiments, and that he took portraits. There was a society in Birmingham called 'The Lunar Society,' comprising amongst its members Watt, Wedgwood, Priestley, and others. A letter was written to this society by Sir William Beechey (or Beachy), the portrait painter, expressing a hope that the then photographers would not disclose their process lest the art of portrait painting should come to an end. There is much other collateral information on this curious subject which has been procured; and inquiries are being still prosecuted. You may probably aid in the investigation. The information is so startling as to seem almost incredible; yet it is true. Of course iodine could not have been used, as it was not then known."

Let us see how this strange discovery bears on the history of

photography. It seems but the other day that we were startled by the announcement that a Frenchman had exhibited to the *savans* of Paris beautiful pictures, mostly architectural, produced in the camera obscura, upon plates of silver or plated copper. The announcement was a surprise to the civilised world, and France purchased the secret of his process from Daguerre, and presented it to the country. The process, when disclosed, turned out to be in brief, the following:—A plate of silver or plated copper was carefully cleaned and polished, and exposed for a short time to the vapour of iodine. It thereby became coated with a film of iodide of silver. This plate was exposed to the luminous image of the camera, and an impression was produced upon it, not visible to the eye, but made evident or developed, by exposing the plate to the vapour of mercury. The picture was fixed, or made permanent, by being washed with a solution of hyposulphite of soda, by which the film of iodide of silver was removed and all sensibility to light destroyed. This beautiful process, although now superseded even in France by the invention of our countryman, Mr. Fox Talbot, was the first really practicable photographic process; the first, that is, available for general use. Its results, moreover, are of astonishing beauty.

It has long puzzled the student in photography to account for Daguerre's invention. He does not appear to have been a man of other than very humble scientific attainments, and his subsequent contributions to photography were puerile and worthless. By what course of thought or experiment was he led to this singular process? He never gave any information on the subject. He died and "made no sign."

This discovery relative to Watt's experiments, added to what Niépce had done prior to Daguerre's invention, seems to bridge over the difficulty very satisfactorily. If it be granted that Daguerre had learned what Watt had done (and the known intercourse of the Birmingham *savans* with their Parisian *confères* renders this probable), the course of Daguerre's researches seems very plain. Let us recall the facts that Daguerre had never devised any photographic process until after he had entered into partnership with Niépce, that Niépce had invented a good but slow process, and that it was not till after Niépce's death that Daguerre's process was invented. Niépce's process was this; he spread upon a sheet of black glass a varnish made by dissolving bitumen in oil of lavender. This plate was exposed in the camera, when the portions of the hardened varnish on which light had acted, were bleached and made insoluble. The faint image produced was strengthened by plunging the picture into oil of lavender, which was absorbed by the unchanged portions of the bitumen, which were either dissolved off or made more transparent, and the picture was strengthened by the more perfect expression of the black glass constituting the dark parts of the picture. Subsequently Niépce exposed the picture to the vapour only, of the oil of lavender, and obtained the requisite vigour.

The points of similarity between Niépce's and Daguerre's process are striking; the use of a surface which, by its blackness (the black polish of the silver), constituted the dark parts of the picture, the coating with a film acted upon by light, the developing or strengthening the impression made, by subsequent exposure to a vapour. When Watt's experiments were made, iodine had not been discovered; and, it is to be presumed, that his silver plate was coated with chloride of silver, the only silver salt then known to be powerfully affected by light. Subsequently iodine was discovered—an element belonging to the same natural family as, and exceedingly analogous to, chlorine. Moreover, it had been put on record by an English chemist, that iodide of silver produced in the moist way was exquisitely sensitive to light (although the necessary conditions of its sensitiveness were overlooked). With all these facts, which were known at the time, and which, it may be readily supposed, were collected by so enthusiastic an inquirer as Daguerre, a man whose devotion to his hobby very nearly procured for him a place in a lunatic asylum: with these facts the construction of his process becomes very easy. A silver plate exposed to the newly-discovered iodine, instead of being treated with chlorine, as practised by Watt, would produce the compound iodide of silver, already known to be more sensitive than the chlorine. But on making the experiment of exposing this plate in the camera, Daguerre must have found that no image was produced; yet iodide of silver made in the moist way was highly sensitive, and the iodide of silver made in the dry way could hardly be believed to be wholly insensitive; there would, doubtless, be an impression, although not visible. But

Nièpce had shown how very feeble pictures could be strengthened by exposure to vapours which would act on the sensitive surface. What more natural than that Daguerre, before abandoning the iodide of silver, should assure himself, either that there was or was not an impression produced on the plate, by exposing it to the influence of something which would attack it, and which might be supposed to attack it differently in different parts, if the light had really produced any change in the nature of the film. Had he pursued this course of thought, he would inevitably be led to think of mercury, which so readily amalgamates with silver. Had he applied a dilute solution of proto-nitrate of mercury, he would have found a picture present itself, but he does not appear to have tried this. The example which Nièpce had set him of applying a vapour was the method he resorted to, and, as is known, with a success at which he himself must have been startled.

But we must not pursue the subject further. Whether the production of pictures on silver by Watt was ever published, we do not know; probably we soon shall know. If it was not, his doings were certainly known to his scientific brethren, some of whom were in correspondence with French savans, and were members, as we believe he was, of French learned societies. But for the length to which it would prolong these remarks, we should have liked to dilate somewhat fully on what we must only note very briefly—another aspect of the curious discovery made respecting Watt and his photographic experiments. Our readers must have heard of photographs having been obtained in colours; that is, pictures in which not only the light and shade, but the colours of natural objects are reproduced. These results, obtained principally by the researches of M. Nièpce de St. Victor, are produced upon plates of silver, coated with chloride of silver, the film of chloride of silver being produced by electrolytic action, and afterwards heated. Such a film will take the colour of any ray of light which may be for a time allowed to act upon it. How little did Watt suspect, when he was experimenting with his chloride of silver plates, that in a few years these same plates, prepared by a somewhat different process from any he could have employed, would hold themselves ready to take any tint of the rainbow, which may be allowed for a time to fall upon them!

ENAMELLED PAPER FOR CARD PORTRAITS.

We have pleasure in publishing a letter just received from one of our esteemed correspondents, Mr. H. Jocelyn, secretary to the British Embassy at Berlin, in which some further details are given regarding the new enamelled papers, with details of the manipulation. The communication was accompanied by some very finely toned specimens, and some samples of the paper in question, in regard to which we may add one or two words. The paper received from Mr. Jocelyn possesses a much higher surface than that to which we recently referred as having been received from Herr Liesegang, and is of a thicker substance. Contrary to the suggestion of our correspondent, we excited it on a 50-grain bath, which we had in use, and had no difficulty in obtaining brilliant results, which toned well and were in all respects satisfactory. The chief difficulty is the tendency to crack, and that may be obviated by the method pointed out in the subjoined letter.

Regarding the paper we have already tried, we think our correspondent is in error as to the nature of the enamel. Sulphide of ammonium gives no indication of the presence of lead, nor did we find any tendency to greyiness in the toning; the tints we obtained varying from warm sepia to a rich purple black. Whether it be prepared by Schering or not, we do not know, as we have not yet received a promised sample by which to make the comparison. From a sample we have seen of M. Schering's preparation, we think it is probably similar to Herr Liesegang's, if not the same. We append the letter.

"DEAR SIR,—I have been so long a reader, and I hope a profiter by your valuable periodical, that I venture to send you herewith a specimen of the enamelled albumenized paper, which I do not think you can already possess. I observe you mention having received some from M. Liesegang, at Elberfeld. The paper which he uses he derives, I believe,

from the manufactory of M. Schering, of this city, and that paper is enamelled, as it is pretty well ascertained to be, with a preparation of lead, which always gives rise to a certain greyiness when in contact with hyposulphite of soda.

"The specimen I send you herewith is prepared by another manufacturer of this town.

"The enamel in this case is not a preparation of lead, but as it is a trade secret, of course it would not be for me to say of what it consists. You will see by the enclosed couple of prints how exquisitely delicately every detail in the negative is reproduced on the enamel, and how far superior it is for card portraits and stereoscopic slides to the albumenized paper.

"Its use is not unattended with difficulties, and, considering the wholesale manner in which our photographers of cartes de visite print their negatives, I fear it will be some time before it is adopted by many of them.

"In the first place, the silver bath should be made of 1 in 5, or of nearly 96 grains to the ounce, in order to obtain the most brilliant effects. It should be of pure recrystallized nitrate, and not the concentrated refuse of old nitrate baths, as I have learnt to my cost, in which case it will not tone at all.

"The enamel paper must never be rolled up, but be always kept in a flat portfolio, or it cracks all to pieces.

"An arrangement must be contrived to prevent it from curling when drying, either by straining it in a light frame of wood, or, what is more simple, by having two strings stretched across the room exactly parallel and one above the other, at the distance from each other of the width of a sheet of the paper to be sensitized, which is then easily kept strained while drying by four clips instead of two at the four corners of the sheet.

"It should not be silvered long, as the solution saturates the albumen on the enamel almost immediately.

"I always tone with gold and a solution of borax used warm, about ten grains to the ounce to each grain of gold.

"It tones rapidly, producing the colours of the enclosed.—I am, dear sir, very faithfully yours,

"NASSAU JOCELYN,

Secretary to the Embassy.

"British Embassy, Berlin, April 10, 1863."

A further letter, after some remarks on the identity of Schering's and Liesegang's paper, adds:—"You must be careful in pressing the cards when finished. They must pass over a steel plate, and not only between rollers, which would crack the enamel."

PHOTOGENIC ACTION AT DIFFERENT ALTITUDES.

MR. GLAISHER, who has recently resumed his balloon observations, in his last ascent made some photographic experiments in illustration of the amount of actinism at different altitudes, presenting very curious results largely at variance with those obtained by Mr. C. Piazza Smyth on Teneriffe. Mr. Glaisher, in a communication to the daily press, says:—

"For the purpose of learning something of the action of the chemical rays of light, I took slips of sensitized photographic paper, having arranged that similar slips, made at the same time, should be exposed at the Royal Observatory, Greenwich, and the amount of coloration in one minute noted every five minutes, so as to have some simultaneous observations with the experiments I might be able to make in the balloon. The paper in the balloon was exposed to the full rays of the sun, and with this remarkable result, that when above three miles high the paper did not colour in half an hour so much as it did in the grounds of the Royal Observatory in one minute.

Whilst Mr. Glaisher finds that the actinism on *terra firma* at Greenwich is thirty times greater than it is at an altitude of upwards of three miles, Mr. Piazza Smyth, in his Teneriffe experiments in 1857, found a progressive actinic intensity with each increase of altitude. "The average times," he

says, "of getting a good picture of a standard subject, in average illumination, were represented by 7 at the sea level, by 5 at the 8,900 feet station, and by 3 at the 10,700 feet station." Possibly varying temperature and other conditions may have affected the results in some degree. Of the temperature on Saturday last, Mr. Glaisher observes:—

Just before leaving the earth the temperature of the air was $61\frac{1}{2}$ deg. At the height of one mile the thermometer read 41 deg.; but we had passed up so quickly, that it is most likely that this reading was higher than the true temperature. At the height of two miles the reading of the thermometer was 32 deg.; at three miles the temperature was 21 deg.; at four miles 16 deg.; and at the highest point reached was 12 deg., which was the lowest temperature we experienced.

The results generally confirm the law as found by the combination of all the preceding experiments, viz.: That the theory of a uniform decrease of temperature with elevation must be abandoned.

The air was dry before starting, and, as found in all the preceding experiments, was very dry at heights exceeding four miles.

Clouds were reached at the height of one mile, and on passing above them, the sea of shining white clouds extending to the horizon, was, as usual, very fine.

The following paragraph from Mr. Glaisher's letter will interest some of our readers:—

From 2.15 to 2.31 I devoted myself almost entirely to observing the black lines in the solar spectrum; between these times the balloon was revolving once in five minutes. I succeeded in adjusting the slit of the apparatus to the sun, and kept my eye to the telescope whilst the balloon completed three revolutions. When the light entered the slit from the sun itself the lines in the spectrum were innumerable. All those I saw before leaving the earth were visible, and many more. The nebulous lines (H) were both seen, and the spectrum a good deal lengthened at the violet end. At the red end (A) was visible. When the light came from the sky in the immediate vicinity of the sun the spectrum was shorter, but all lines were visible from (B) to (G). On passing from the sun the spectrum shortened very quickly, and when opposite to the sun there was no spectrum—in fact, no light at all.

The courage and perseverance with which Mr. Glaisher, whom our readers will be proud to remember is an ardent and accomplished photographer, prosecutes these ascents for scientific observations is worthy of all admiration. That it is not by any means devoid of danger, and that it demands high courage and great self-possession is abundantly proved by the events of the last ascent, to which only the skill of the aeronaut and the calm presence of mind of all concerned prevented a disastrous termination. The ascent commenced from the Crystal Palace at 1.17 p.m., and the earth was reached again at 2.50 p.m., at Newhaven, on the south coast. The entire distance of nearly sixty miles, in round numbers—we do not speak by the card—besides the ascent and the descent, being done in about an hour and three-quarters, and a descent in the sea being only barely escaped. We append the exciting account of the descent:—

After reaching the height of four miles, and we had determined we were moving directly towards the coast, Mr. Coxwell continually applied to me for the readings of the barometer, and directed our companion, Mr. I——, to keep a sharp look-out for the sea.

Immediately after we attained an elevation of four and a half miles Dr. Coxwell let off some gas, and said he felt assured there was not a moment to be lost in getting within view of the earth.

Mr. Coxwell again let off gas rather freely, so that we descended a mile in four minutes.

At 2.46 we were two miles from the earth, the barometer reading 21.20 inches, when Mr. Coxwell caught sight of Beachy Head, and exclaimed, "What's that?" and then the coast through a break in the clouds, and exclaimed, "There is not a moment to spare, we must descend rapidly, and save the land at all risks." It was a bold decision, but we were in a critical position, and I do not see what else could have been done.

Mr. Coxwell now used the valve with a degree of freedom which would have alarmed any one who had not perfect confidence in his skill.

I was requested to pack up my instruments as quickly as possible, and then to assist in getting ready a large amount of ballast to throw away at the last moment.

On breaking through the clouds we appeared to be already over the water, but as the ground came up to us, or seemed to do so, we found there was land beneath. Mr. I—— rendered important services in letting up the neck lines, and in clearing the ballast for immediate delivery, so as to lessen the violence of the descent.

When orders were given to put out sand, we did so simultaneously, which gave a favourable check, and, as the lower part of the balloon itself assumed a parachute form, the shock was not so bad as might have been expected. Most of the instruments were broken, owing to their delicate construction, yet, strange to say, the glass vessels of air, collected at the highest point for Professor Tyndall, remained uninjured, as did some bottles of lemonade which Mr. Coxwell had placed in the ear.

We descended the last two miles in four minutes, and had we done so less rapidly the land would have been missed altogether, and we must have fallen into the sea. The descent was within half a mile of the station at Newhaven.

ON DEVELOPMENT WITH FORMIC ACID.

BY DR. MONCKHOVEN.

I HAVE prepared formic acid in the following manner:—I kept a mixture of glycerine and oxalic acid for three days in a glass retort at a temperature of 220° to 230° F. The crude product of distillation was treated with soda, and dried in order to free it from the glycerine and other volatile substances, carried over during distillation. The formiate of soda thus obtained was treated with sulphuric acid, diluted with half its volume of water, and heated in glass retort furnished with a condenser. The formic acid obtained possesses a penetrating odour, is perfectly colourless, and marks 1.12 with the densimeter, and is a very concentrated acid.

I then prepared two samples of pyrogallie acid, exactly following the proportions indicated by M. Claudet, viz.:—

Water	225	parts.
Alcohol	20	"
Formic acid	30	"
Pyrogallie acid	1.20	"

The second sample was prepared in exactly the same manner, except replacing the 30 parts of formic acid by 30 parts of dry crystallized acetic acid.

Lastly, I prepared a bath of iron also according to the usual proportions, viz.:—

Sulphate of iron, quite pure	...	5	parts
Water	...	100	"
Crystallized acetic acid	...	2.5	"
Alcohol	...	5	"

I then compared the development of plates exposed in a stereoscopic camera with compound lenses, furnished with a spring cap. I exposed eighteen plates in succession; the weather was very favourable, as I operated under a cloudless sky.

The result of my experiments is as follows:—

1st. That sulphate of iron admits of a shorter exposure in the camera than pyrogallie acid, whether the latter contains formic acid or acetic acid.

2nd. Development with pyrogallie mixed with formic acid is not more rapid than when acetic acid is added to it.

3rd. The negative developed with pyrogallie acid mixed with formic acid appears quick, but the formic acid tends to reduce the silver from the nitrate, and to produce on the film a grey deposit of metallic silver. I believed, upon a superficial examination, that there was greater intensity of the picture, but an examination by daylight by transmitted light satisfied me there was not.

My own opinion upon this point is as follows:—

1st. That formic acid alone, without pyrogallie acid, in

not causing the image to appear by reducing the silver from the nitrate, produces a veil which gives to the iodide of silver a grey colour.

2nd. That formic acid added to pyrogallic acid, acts in the same manner, and that the exposure in the camera is the same as with the ordinary formula.

These experiments were made on the 2nd April, with two nitrate of silver baths, the one neutral, the other acidified by nitric acid.—*Le Moniteur de la Photographie*.

ENLARGED PHOTOGRAPHIC TRANSPARENCIES FOR ORNAMENTAL WINDOWS, &c.

BY DR. TAYLOR.

[We are favoured by Dr. Taylor with the following excellent remarks on the capacity and scope of photography, and especially as to its probable future position in decorative art, which were made at the last meeting of the Glasgow Photographic Association on the discussion on Mr. Macnab's interesting paper on "Copying and Enlarging."]

DR. TAYLOR said that the paper which had just been read, related to a subject which to him appeared to be of great interest to photographers at the present time. He believed that photography could not be said to be in its infancy in the sense in which some persons used the term, because he thought that it had reached very considerable maturity; so much so, that, in some respects, comparatively little remained to be accomplished. They had already reached results so beautiful and so nearly perfect that he feared the strides to be made in future years would not, in regard to some walks of the art, be so great as those of the past. Confident expectations were frequently expressed regarding the probability of getting the pictures in the natural colours; he confessed that in this direction he had little hope. From the nature of the chemical processes employed few colours could be imitated in the film. How, for instance, were they to give silver the substance at present forming the image, all the varieties of hue assumed by natural objects. As long as the picture consisted of a silver deposit he had no hope of seeing any other colours than those which can be assumed by silver. The same remarks may apply to any other single substance which might be substituted for silver; in fact, he could not see how it was possible to get the infinite variety of natural tints in a photographic picture, and the mere power to imitate a few colours would be of little value. But as to future advancement, he was very sanguine in the progress of the art in another direction, viz., as regards the size and boldness of effect of the pictures. They were all well aware that the art of the painter would be confined in its results if it were limited to miniatures or to cabinet-sized pictures. It was only in large gallery paintings or in great dramatic pictures, as seen in churches and other public buildings, that the art gained power to make its deepest impressions on the mind. The painted ceilings became a part of the architecture, and produced an effect on the spectator which could never be obtained by small work. Photography had been hitherto confined to small work, such only as could be seen by close inspection, and dependent for its effect on minutiae of detail, and it was only very recently that it had attempted to reach a grander development, and to produce results which large size and breadth of effect alone could give. The processes of enlargement, which had been that evening so well described, sought to produce such work that no one could pass it without being impressed with its presence. It would now seem that small pictures, such as those exquisite little cards or stereoscopic views now so well known, can be enlarged to almost any extent. No one could doubt but that this was a great step in advance, and that photography would thus be enabled to take up a more extended, and perhaps a higher position. Those transpa-

rencies, such, for instance, as the one before the meeting, would come to be taken advantage of for the decoration of buildings. The house-painter at present exercised his faculties in decorations of this kind, and so long as he confined his efforts to ornamental scrolls or geometrical patterns, succeeded moderately well; but when the human figure or other object, requiring accurate and subtle drawing, was attempted, the results were too often anything but beautiful or instructive. Drawing was an art in which few obtained perfection, but photography promised to bring a higher kind of decorative art within easy reach. If glass doors and pannels could be ornamented with large sized photographs of appropriate subjects, he had little doubt that they would soon supplant the daubs that at present too frequently appear in such situations. Then, again, as regards our stained-glass windows, he thought photography would yet have an important part to play. The kind of art at present in use was excessively costly, we paid thousands of pounds for it. He would not wish publicly to say anything by way of depreciating works which were so highly paid for, and on which so much labour had been bestowed, but to a society of photographers the case was different, and to them he would confess, that, in his opinion, such works, compared with photographs, were, in most instances, merely barbarisms. In past ages, no doubt such work served its purpose, and as a relic of the past it deserved our regard; but he had no doubt but that appropriate photographic transparencies of well chosen subjects, delicately tinted by coloured glass placed behind them, would be far more effective and beautiful than the incongruous and improbable-looking pictures at present too often seen occupying prominent situations. Let us have such pictures to take the place of the frequently ill-drawn and glaringly-coloured figures which had long been the representations on stained glass. Colours were much alike in all ages, and though the scenes represented were long past, this ought to form no reason why the pictures should be made of such hues and arrangement as to have only a faint resemblance to anything that ever could exist, or that modern art should still be tied down to imitate the colours and designs of a past age. The fact seemed to be that glass painting was an art which, as we had borrowed it from our ancestors, we were afraid to improve through dread of innovation. We have it from antiquity in the same way as we have received the symbols of heraldry, and as relics of antiquity we tolerate or even venerate them, but as for the received system of decoration on windows he confessed that he would rather see it among the dust and cobwebs of an old church than as a thing to be imitated or followed at the present time. But the question for us is, could photography do better? He had tried the fine head of Tenyson with tinting of colours and surroundings of coloured draperies of stained glass, and he thought the effect much finer than with the conventional heads employed by the glass-stainers. As to the landscapes, he had hopes that they would soon be produced of such a size as to be seen at once by a whole company of spectators; they would then, if executed with all the precision, multiplicity of detail, and truthful interest which photography could give them, and if made of such dimensions as to cover the end of a good-sized room, become among the grandest achievements of any art. To look at them would, indeed, be next to travelling to the spots which they represented. The process by which this enlargement could be produced had to him a peculiar interest. The first specimen of its results was one executed a few years ago by the author of this paper. He was anxious to possess a large photograph of Holyrood Chapel, but no such picture had been taken. Mr. Macnab got hold of a paper stereograph of the required subject, and by the process they had this evening heard described, soon succeeded in producing the enlarged picture which some of them had lately seen in the dioramic apparatus. It was most successful, every detail was faithfully reproduced and without visible distortion, giving

great promise as to the future results to be expected from this process of enlargement, which he could not but regard as one of the most fertile fields for the future enterprise of photographers.

ON THE DECOMPOSITION OF COLLODION.

BY DR. VAN MONCKHOVEN.

If there exists a subject upon which numberless gratuitous hypotheses have been written, it is surely this. To prove it, let any who is thoroughly acquainted with chemistry take any bulky treatise on this science, and turn to the pages upon which ether and alcohol are described; he will read that iodine and bromine act at high temperatures upon these substances, producing others, the names of which are very sonorous, and, by the aid of the imagination, very long articles are written upon the decomposition of collodion, which have a very learned aspect, but which, in fact, make true chemists smile, for they contain all sorts of things except the truth.

Some years ago, when the nature of collodion was less known, we fell into the same error as that described, but now that more exact and complete studies have guarded us against the vagaries of imagination, we have adopted the principle of admitting facts only when they are based upon experiment, which, in a scientific point of view, is always a prime necessity. We will, therefore, now examine the decomposition of collodion, sustaining ourselves upon precise and irrefutable experiments, and not upon suppositions more or less specious.

What is collodion? It is a solution of pyroxyline in pure alcohol and ether, to which an iodide is added. It is generally remarked, that collodion, composed with pure materials and recently prepared, yields, a few days after its preparation, results very different from those obtained when this collodion has been kept a very long time—several months for example. These differences are as follows:—

New collodion gives in the nitrate bath a white film, the opacity of which is considerable, and the rapidity of luminous impression very great; but in general the pictures are not very strong (with sulphate of iron). All the details of the image come well, but the sky and strong lights in the model do not acquire much opacity.

Old collodion, on the contrary, yields films that are almost transparent, not very quick under exposure, but the pictures, on the contrary, are very intense.

There are other differences between new and old collodion, such as the following: *new* collodion, when dry, will not give pictures by washing the film after sensitizing; *old* collodion, on the contrary, does yield them. With new collodion, the picture developed with sulphate of iron is entirely soluble in nitric acid; with an old collodion, the image is not entirely soluble, which will be explained immediately.

Photographically speaking, then, there exists an essential difference between new and old collodion, and the object of this article is to ascertain the cause of this difference.

We will commence by establishing this important fact, that contrary to the generally received opinion, a collodion minus the pyroxyline, that is to say, an ethero-alcoholic solution of an iodide, will keep for an indefinite time. We possess a solution of iodide of potassium in ether and alcohol prepared many years ago; this solution is scarcely tinged with iodine, and when a little pyroxyline is added to it, it works marvellously well. This fact serves us as a basis to prove that everything which has been written upon the decomposition of collodion is erroneous; for how can traces of iodine (the quantity which colours the collodion is less than 1 gramme in 1000 litres), exercise a decomposing effect upon the collodion, when they are so feeble as almost to escape analysis.

But, on the other hand, let us take a simple collodion, consequently without an alkaline iodide, and we shall observe the following facts:—

The collodion begins by becoming more fluid, and acquires a peculiar odour of nitric ether. When kept a very long

time, it gives, when poured on the glass plate and sensitized in the nitrate of silver bath, a white film which yields pictures in the camera! And yet there is neither iodide nor bromide present!

It is, therefore, neither free iodine, ether, nor alcohol, which act in the decomposition of the collodion; it is the pyroxyline. But what takes place with it?

When the sulphuric and nitric acids act upon the cotton, not only is gun cotton formed, but also a substance greatly resembling it, which is *nitro-glucose*, as shown by Mr. Hardwich. Between *nitro-cellulose* (pyroxyline) and *nitro-glucose* (nitre-sugar), there is a very great analogy with regard to their chemical properties; but nevertheless, *nitro-glucose* produces certain effects which have escaped the rare penetration of Mr. Hardwich; they are the following:—

Nitro-glucose is obtained by mixing 300 parts of concentrated sulphuric acid with 200 parts of nitric acid, specific gravity 1.5, and 100 parts of ordinary sugar in powder. After two or three minutes' action, the plastic mass is washed in water, and pressed together with the fingers. It is then washed in warm water, dissolved in warm concentrated alcohol, and precipitated by water. After the lapse of a few days it is deposited at the bottom of the vessel under the form of a gummy mass.

The alcoholic solution of nitro-glucose, agitated with caustic potash, *browns*, and exhales an odour of *burnt sugar*. Now *simple collodion, kept several months, exhibits exactly the same characteristics.*

The alcoholic solution of nitro-glucose possesses very curious properties, the study of which is of the greatest importance to photography. This solution is colourless, and when added to collodion, it produces no effect. *It is not disturbed by the addition of an alcoholic solution of nitrate of silver.*

Kept several days in a corked bottle, the solution which was at first colourless with a purely alcoholic odour, becomes of a *rose* colour, and acquires the peculiar odour of old collodion, that is to say, of nitric ether. But more; this rose-coloured solution now precipitates nitrate of silver, and added to a recently prepared collodion, imparts to it immediately all the properties of old collodion: namely,

1. Less rapidity.
2. Very intense negatives.
3. The property of acting when dry, with a simple washing after sensitizing.
4. Transparent sensitized films.
5. Negatives which, develop either with iron or with pyrogallic acid, and not are entirely soluble in nitric acid.
6. A peculiar odour.
7. A red colour due to a little iodine set at liberty.
8. A great tendency to solarization.

Lastly, there is a fact which confirms our theory. An old collodion, prepared several years, precipitated by an alcoholic solution of nitrate of silver, instead of giving a precipitate formed only of iodide of silver, gave a precipitate six times more considerable, and the properties of this salt are *the same* as those obtained with the decomposed nitro-glucose. Doubtless this is the product which changes so profoundly the properties of collodion.

The decomposition of collodion arises then, not from the action of the acids accidentally present in the pyroxyline or ether, acids which have the effect of setting free a little iodine which scarcely changes the properties of the collodion, but from the slow decomposition of gun-cotton in presence of alcohol. Then the gun-cotton produces nitrous or nitric acid, which forms a large quantity of nitrate of ethyle (nitric ether), which ether imparts to the old collodion its well-known odour; moreover, the quantity of collodion diminishes by this fact, the solution becomes more fluid. Lastly, the product of this decomposition is an organic body of a composition hitherto unknown, but which is susceptible of forming with nitrate of silver and iodide of silver, a compound sensitive to light, both in the humid and the dry state. The developer, instead of producing upon

a film of this collodion an image composed solely of pure silver, forms, on the contrary, an image constituted of an organic substance analogous to albuminate of silver blackened by light; also, the developed picture is imperfectly soluble in nitric acid. Every one possessing old collodion can easily prove for himself the truth of the facts and conclusions arrived at.—*Le Moniteur de la Photographie*.

THE NEW ART OF AUTO-TYPOGRAPHY.

BY GEORGE WALLIS.*

As the new art-process for the reproduction of drawings to which I am about to call attention, and as far as possible describe and illustrate before you, is based in principle upon a process of an analogous character, by which certain classes of natural objects are engraved and printed, popularly known as Nature Printing, I think it desirable from my personal connection with the two gentlemen who certainly originated the direct method of Nature-Engraving, as I prefer to call it, in this country, and my knowledge of their early efforts, to endeavour briefly to correct a wrong impression which I believe to have been unintentionally given, through an imperfect knowledge of the true facts and the dates at which the first experiments were made in England.

In a paper read at the Royal Institution, 11th May, 1855, by the late Mr. Henry Bradbury, to whose ability, energy, and perseverance, the art of nature printing owes so much, and also in a more recent publication, the early attempts to obtain impressions from plants, &c., are carefully traced up. In these papers Mr. H. Bradbury gives the credit, which is evidently due to a Danish goldsmith and engraver, Peter Kyhl, of Copenhagen, as having been the first to produce impressions in metal plates direct from natural objects; but whilst honourably seeking to do justice to an ingenious man, who unfortunately died in 1833, the year in which he made his invention known, he does a certain measure of injustice to the late Mr. Richard Ford Sturges and Mr. W. C. Aitken, of Birmingham, on the assumption that the experiments made by the former in August, 1851, and the latter in the spring of 1852, were based upon a knowledge of what Peter Kyhl had done. I have no hesitation, therefore, cognisant as I am of nearly all the earlier efforts in this direction at Birmingham, to declare that neither Mr. R. F. Sturges nor Mr. W. C. Aitken knew anything whatever of Kyhl or his experiments, and did not even know that such a person ever existed prior to the publication of the paper read by Mr. Henry Bradbury at the Royal Institution, more than three years after Mr. R. F. Sturges' patent for the ornamentation of metals by pressure, which process he claimed as his invention, had been taken out.

I have felt it my duty to state this, because I purpose bringing out the true dates in connection with the invention of the process of nature printing, leading as this process does to that which I am about to describe and illustrate, and of which I claim to be the inventor.

That the Danish goldsmith and engraver, Peter Kyhl, did, in the year 1833, exhibit at the Exhibition of Industry, held at Charlottenberg, various productions in silver, decorated by a process described in a manuscript, entitled "The description (with forty-six plates) of a Method to Copy Flat Objects of Nature and Art," dated 1st May, 1833, and that the plates "represented printed copies of leaves, of linen and woven stuffs, of laces, of feathers of birds, scales of fishes, and even serpent skins," we have the authority of the late Mr. Henry Bradbury, based on that of Professor Thiele, and therefore we may accept it as a fact; but that this fact had anything to do with the experiments instituted at Birmingham, in August, 1851, by Mr. R. F. Sturges, in the engraving of lace, and early in 1852, by Mr. W. C. Aitken, in engraving skeletons of leaves, feathers, &c., by placing the objects between two plates of metal and subjecting them to pressure by steel rolls, I emphatically deny. The truth is, Kyhl's process had been evidently forgotten, and his manuscript, buried in the archives of the library at Copenhagen, was not dug up until the Imperial Printing Establishment at Vienna had given dignity to the process of nature printing, and Mr. Henry Bradbury had brought the invention from Vienna, where it was practised, and, by his skill and ingenuity, had begun to produce the works which are so worthily associated with his name.

The facts are these. In August, 1851, the late Mr. R. F. Sturges made some experiments in direct engraving, by placing pieces of lace between two Britannia metal plates, and passing them through a pair of steel rolls, revolving at a suitable pressure, his object being to devise some cheap and rapid process for the ornamentation of metals. A little specimen in one of the frames before you is an impression printed from one of the plates so engraved at this period. Mr. Sturges took out a patent for "ornamenting metallic surfaces," based upon the results he had arrived at. This patent is dated 24th January, 1852.* Specimens were shown about as curiosities, especially impressions printed from the plates. In assisting to bring this patent into operation, in the establishment of Messrs. R. W. Winfield and Son, Cambridge Street Works, Birmingham, Mr. W. C. Aitken made his first experiment on natural objects with a skeleton leaf, picked out of a roadside brook, early in the spring of 1852. An impression of this, together with one of the two plates, which Mr. Aitken presented to me, are now before you. This result was shown to me in a day or two after it was produced; therefore, I am speaking from experience, and not from hearsay, or upon any authority. Mr. Aitken subsequently brought the further results of his experiments before this Society, in a paper read in February, 1854, and printed in the *Society of Arts Journal*, vol. ii. p. 227.

In Mr. Henry Bradbury's paper, read at the Royal Institution, he says, "In the Imperial Printing Office at Vienna the first application of taking impressions of lace in plates of metal by means of metal rollers, took place in the month of May, 1852. It originated in the Minister of the Interior, Baumgartner, having received specimens from London, which so much attracted the attention of the Chief Director, that he determined to produce others like them." Now we all know what the Imperial Printing Office of Vienna showed in the Great Exhibition of 1851; and, beautiful, and even wonderful, as the specimens were, that there was nothing in any way approaching to nature printing. The Austrian commission, however, was busily employed in London until the end of 1851 or beginning of 1852. Its members visited Birmingham, as our foreign friends usually do on these occasions, as a relaxation from heavy duties, and from a laudable desire to obtain information.

Mr. R. F. Sturges was not a man to "hide his light under a bushel," and therefore I have little doubt that the specimens of impressions of lace from plates engraved by him were sent to the Austrian Minister of the Interior, being obtained, either directly or indirectly, from Mr. Sturges immediately after he had secured himself in England by patent. If not, where did they come from? No one else in this country had at this period done anything of the kind. Peter Kyhl had been dead and his experiments at Copenhagen forgotten, where alone they had been known eighteen years before.

If we compare the date of Mr. R. F. Sturges' patent, January 24, 1852, with the date given by Mr. H. Bradbury, May, in the same year, as the period of the first experiments at the Imperial Printing Office at Vienna, it will be seen at once that Mr. Sturges had no object in the concealment of his process or its results, for three months before anything was known or done at Vienna.

In making these remarks, I do so for the honour of Birmingham, and from a strong conviction, based on a personal knowledge of the facts, and not from hearsay, that the action of the Imperial Printing Office at Vienna was induced by the successful experiments made in Birmingham in 1851-2.

Having, thus, as an act of justice to an ingenious manufacturer, stated these facts as to the independent re-invention, at least, of this process, assuming Peter Kyhl's to have slept—as it really did—not only from 1833 to 1851, but, in fact, to 1855, when it was brought forward through the instrumentality of Professor Thiele, I may now briefly allude to the several processes employed for the reproduction of flat natural objects by means of metal plates and the printing press: the nature printing of Dr. Dresser by transfer from leaves of plants, &c., to paper direct, and his process of transfer to lithographic stones and printing therefrom, being outside the present question, although very interesting and useful in many points.

In 1847, Dr. Branson, of Sheffield, made a series of experiments, commencing with taking impressions of leaves in gutta-percha, from which he cast a brass mould to print from. An electrotype plate could also be obtained. In 1851, Dr. Branson brought this interesting subject and his processes before the Society of Arts.

* *Society of Arts Journal*, April 17, 1863.

* Patent No. 13,914.

After the Imperial Printing Office at Vienna had experimented upon lace, &c., in 1852, as already mentioned, we have Mr. Henry Bradbury's authority for stating that gutta-percha was tried by Andrew Worring, in whose name the patent was subsequently taken out. No doubt this plan was derived from Dr. Branson. This failing, he, says Mr. Bradbury, "employed," as Peter Kyhl had done before him, "soft lead plates." Yet, probably, Worring was as innocent of any knowledge of Kyhl's doings as Mr. Sturges was. This Mr. H. Bradbury acknowledges with regard to the former, and it is deeply to be regretted that he did not do so in regard to the latter, as I think that Worring, being connected with such an establishment as the Imperial Printing Office at Vienna, was much more likely to know of the existence of Peter Kyhl's manuscript in the Royal Library at Copenhagen, than a busy manufacturer at Birmingham. Mr. Henry Bradbury's process was taken from that practised at the Imperial Printing Office at Vienna, where he was engaged for a period, with such improvements as his great ingenuity and perseverance enabled him to introduce; and we see the result in the magnificent volumes published by Messrs. Bradbury and Evans.

In all these processes, however, the plate from which the impressions had to be printed was an electrotype copy of the soft lead plate in which the object was engraved, and a considerable amount of labour and skill in burnishing and touching up had to be expended before the plate was fit to yield a satisfactory impression.

This is not the case with the direct process, or with Mr. R. F. Sturges' method of copying lace, &c., and more particularly as carried out in reference to natural objects by Mr. W. C. Aitken. The impressions of the most delicate skeleton of a leaf, or a feather with its down, are impressed direct in all their delicacy and the plate is ready to print from at once.

It was this fact which led me to the experiments which have resulted in the process I am now to describe, for, on seeing the first specimen of a feather engraved by Mr. W. C. Aitken, early in 1852, I asked myself mentally, "If the down of a feather can be made to impress itself in a metal plate, and print, why not a drawing?" The next question was, "How to do it?" Urgent duties prevented any experiments until the winter of 1858. The result of these experiments I shall now give in detail.

No want has been more strongly felt in the arts than some easy rapid, and direct method by which the spirit and mental impress of the artist's own hand could be reproduced in a metal plate or type, either in intaglio or relieve. I remember reading, when a youth, in some old edition of the Life of Albert Durer, that he had solved this problem and had a secret method which died with him by which he could transfer a drawing to a metal type and print from it. Whether this was simply a mystical description, by some person ignorant of art-processes, of the ordinary method of etching, in which Durer was such an adept, I cannot say, but it made a deep impression on my mind, and the question how to bring about such a result was for years a subject of interest and speculation with myself, as it has no doubt been to hundreds of others. When, in 1842, Mr. Palmer commenced his experiments in glyptography, some friend, knowing my propensity to experiment in this direction, sent him to me, and I believe I executed for him the first drawing produced by his process, in which lines were drawn in imitation of etching, or the *fac-simile* style of wood engraving. After several experiments, however, not seeing my way to satisfactory artistic results, I declined to devote any more time to this process. I have ventured to name this as showing that my attention was by no means first drawn practically to this question, when the success of the direct nature engraving of my friend, Mr. W. C. Aitken, in 1852, directed it into a new channel. In fact every process of the kind had been practically examined and tested—etching on copper and steel, lithography, zincography, the anastatic process, the paneionography of Gillot, shown in the Exhibition of 1851, from which so much was expected in surface printing, had all had attention. The matter was, therefore, not taken up blindly, except in one point, and that a most important one, for every single step of the solution of the problem had to be taken practically in the dark, as there was no experience in the same direction to suggest, still less to guide, in a single experiment; and even now, after four or five years' experience, I rarely make an experiment without gaining some additional light, which either helps the certainty, or extends the operation of the process. I beg, therefore, most distinctly to state, that I do not bring this before you as a perfected process, but simply as a method which, so

far as, experience has gone, has produced certain undeniable artistic results, and as containing, as I believe it does, the elements of far higher, much wider, and more practical issues in the future. I trust no one will tell me that because the effects shown on this occasion are only produced in *intaglio*, that it would be much better for economical purposes to produce them in *relievo*, and thus suit them to the immense demand for surface printed illustrations. Of all this I am quite aware; but having so far accomplished one phase of the invention and undertaken to explain it, I shall confine myself to that. Should I, having already made a beginning, solve the other part of the problem, and produce a block where I now only produce a plate, I shall ask for another opportunity to bring that before you in due course. In the meantime our subject is the production of a metal plate engraved direct from a drawing and suitable to be printed from at an ordinary copperplate printing press, or for transfers in certain industrial arts.

(To be continued.)

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, April 22nd, 1863.

At the last meeting of our Photographic Society, Mr. Henner's communication on the modifications he has introduced into the treatment of photographic residues was read. His special aim has been to obviate the inconveniences, in a sanitary point of view, arising from the method hitherto employed for extracting the precious metals from the washing waters. One of the well-known methods adopted consists in immersing in the liquid, which is strongly acidulated, a bar of zinc or of iron. This method is excellent in practice, when adopted with certain liquids, but, if applied to photographic residues, it causes certain decompositions which we should endeavour to avoid.

Hyposulphite of soda and cyanide of potassium, for example, are often found in great quantity in the washing waters. By the action of the acid necessary to attack the zinc, *sulphurous acid* is formed, very irritating to the respiratory organs; and *hydrocyanic acid*, still more dangerous to inhale.

Another process consists in precipitating the gold and silver in the state of sulphides. If the waters are acidulated, which is almost always the case, there is a very intense disengagement of hydrosulphuric acid, when the alkaline sulphide is added. Now, we well know how disagreeable this gas is to respire.

To obviate these inconveniences, which often induce photographers to throw away the washings, or to sell them at a nominal price, Mr. Henner confines himself to *neutralizing the liquids*, and to keeping them in that state. It is easy to ascertain this condition by means of litmus paper. To effect this neutralization, we cannot employ the carbonates which cause a disengagement of carbonic acid, and, besides, are expensive. Caustic potassa and soda must, also, be avoided. Mr. Henner makes use of lime; or, rather, of *cream of lime*. It is thrown from time to time into the liquid residues, and left to settle. Thus, by this very simple method, the gold and silver are precipitated in the state of oxides, better adapted for melting than sulphides. In those cases where we suppose that traces of the precious metals still remain in the liquids after this treatment, it suffices to add a small quantity of alkaline sulphide, which, being employed after neutralization, has not the same inconveniences.

This method, successfully employed for several months by Mr. Henner, presents many advantages, of which photographers will, doubtless, gladly avail themselves.

Mr. Henner also announced that he has studied the method of manufacturing sulpho-cyanide of ammonium, and finds that it is possible to produce this useful product at a very low price. As to the properties, more or less injurious to health,

of this salt, Mr. Heppner has made comparative experiments, not yet completed, which, however, prove that the sulphocyanide of ammonium is far from possessing the poisonous properties of the cyanide of potassium.

M. Potteau exhibited some new proofs, which render his collection of the various types of the human race complete. He has also photographed certain anatomical specimens, which, from their flaccidity, could not be placed vertically: placed horizontally, and photographed from above, their forms are accurately depicted. M. Potteau also exhibited an interesting collection of costumes, views, and types, brought from Siam, by M. Beaufour.

M. Moisson sent some enamelled photographs. He first obtains a transparent positive in the usual way, covers it with yellow ochre, and allows it to dry. The plates are then placed in a muffle, and heated to a cherry red. The image is in this way vitrified, and incrusts in the substance of the glass.

M. Terrail has discovered a very ingenious process, by means of which he separates the coating of albumen containing the picture from the paper, without in any way damaging it. It can be rolled up or kept in a portfolio, and transferred to a glass plate or another piece of paper. This process will be found very useful for negatives and in travelling. M. Terrail obtains this result by parchmentizing the paper.

M. Roman, of Wesserling, sent some proofs executed by his dry process, and recommends the employment of a very minute quantity of pyrogallic acid after washing, as it is important for the preservation of the picture. M. Roman has ascertained that the sensibility of plates prepared by his method is nearly one-half less than that of plates prepared with wet collodion.

M. Meynier writes to the *Moniteur de la Photographie* in reference to the report presented by M. Teissère to the Photographic Society of Marseilles, upon the *sulpho-cyanide of ammonium*, which he (M. Meynier) was the first to propose for fixing photographic proofs without danger to the operator; he says:—"I regret that before publishing that report it was not communicated to me, as it involves the question of a process of manufacture supposed to emanate from myself, and the result of an experiment made in my presence.

"I have nothing to say concerning the essays attempted by the committee, which retains the responsibility of the results it has made known; but I wish to state a fact relative to the fixing experiment made in my presence upon the day, when, upon M. Teissère's invitation, I went to the laboratory of the Society. M. Teissère brought three stereoscopic pictures ready for fixing. Each was divided into two equal parts; the one was immersed in a solution of hyposulphite of soda, the other in a solution of sulpho-cyanide of ammonium. On being taken out of these solutions after fixing, all the halves fixed with the sulpho-cyanide appeared like, as to tint, those fixed in hyposulphite of soda. M. Teissère thought that those fixed in the hyposulphite were whiter than the others. A person present during the experiment, consulted on this point, declared, on the contrary, that those fixed in the sulpho-cyanide of ammonium were the whitest, from which it would appear to result that they did not differ sensibly one from another. This is all I wish to establish at the present time. However, I do not mean to say that the proofs upon albumenized paper may not subsequently acquire a bad tint, when fixed in sulpho cyanide. If it should prove so, we must search into the cause, and the explanation given by M. Teissère of the phenomenon of colouring he observed will still be premature, if not even in opposition to the properties of the salt with which he experimented.

"I have undertaken a series of experiments upon fixing positive proofs, the results of which I shall publish hereafter, if I am not anticipated by operators more skilful than myself, such as MM. Davanne and Girard, who are much occupied with the study of the new fixing salt, and who have already remarked the phenomenon of which M. Teissère

has spoken, but of which they have not yet discovered the real cause."

M. Belitsky gives an easy method of making a specific gravity bottle without its containing exactly 1,000 grains. Take a clean dry bottle of thin glass, with glass stopper, and ascertain its weight, then fill it completely with distilled water at 60° Fahrenheit, and wipe it clean. Then weigh the bottle, and the weight of the water may be easily found by deducting the weight of the bottle. To ascertain the weight of a liquid, fill the empty bottle with it, weigh it, and its specific weight is readily found. For example:—

The empty bottle weighs	...	349.34 grains.
Filled with distilled water at 60°		611.39 do.

Consequently the water weighs 262.05 do.

The bottle filled with alcohol weighs 568.66 do.

Consequently the alcohol = 219.32 do.

By the rule of proportion 262.05 : 219.32 :: 100 : x ;
 $x = 836.9$; which is the specific weight of the alcohol.

Proceedings of Societies.

MARSEILLES PHOTOGRAPHIC SOCIETY.

At the meeting of this Society, held on the 10th ulto., M. Rey gave an analysis of the publications received during the preceding month. He interested the members of the Society by the precise details he gave upon the various steps in progress recently accomplished. The facts upon which he particularly dwelt were:—M. Jeanrenaud's method of toning; M. Belitzki's researches upon the part water plays in collodion; M. Wharton Simpson's observations on the favourable effect of the fumes of ammonia in developing negatives obtained by the tannin process; M. Jeanrenaud's formula for collodion; M. Poitevin's account of his recent progress in carbon printing, &c.

The SECRETARY, in thanking M. Rey on behalf of the Society, called the attention of members to the importance of the facts noticed by the honourable member. He would, he said, sum up in a few minutes those works, the results of which promised to become the most favourable for the future of the new art. Photography, after having slumbered a few months, or rather, having taken that repose necessary for new researches, has awakened with a crowd of new ideas and discoveries, which are at once both conquests over the past and aids to future progress. M. Poitevin, who has so accustomed us to surprises, has startled us with the discovery of the curious reactions due to light. Doubtless, in consequence of other learned researches, we shall soon arrive at a truly practical application of carbon printing.

M. VIDAL insisted upon the practical value of the processes indicated by M. Jeanrenaud, a very skilful amateur, who has obtained very fine pictures by the dry process.

M. DE SIVRAY, director of the photographic operations of the Society, was invited to give an account of the experiments he had made with the water of Patako, sent to the Society by M. Clerville. His experiments show that this compound is very suitable for producing intense blacks in the negatives, where transitions from white to black are unnecessary; for instance, in reproducing plans or engravings. As to negatives with half tone they were less successful. It is true, however, that an intensified picture is never of equal value with a proof the effect of which is the result of a sufficient action of light.

Dr. MONCKHOVEN presented to the Society a copy of his new Treatise on Photography.

M. VIDAL, in the name of the Administrative Committee, proposed that letters of congratulation be addressed to MM. Poitevin, Bayard, and Duboscq, on the distinction they had obtained at the International Exhibition of 1862. This proposal was unanimously adopted.

M. GUIBAULT asked permission to read the draft of a letter addressed to the Minister of State, soliciting of His Excellency that works of art, the result of the application of photography, be admitted to the Fine Art Exhibition.

"MONSIEUR LE MINISTRE,—Among the works invited to be sent to the Art Exhibition of 1863 we do not see mentioned those executed by means of photography. We take the liberty

of addressing you a few remarks on the subject, on behalf of the Photographic Society of Marseilles.

"There is some confusion in the expression which has hitherto been adopted to designate everything proceeding from this admirable discovery, and we do not hesitate to attribute to this fact the omission which we take the liberty of pointing out to you. The term *photography* is employed indifferently both for the science and the art of photography. There is, however, a distinction to be made, and a word to be created. The term 'photographic science' appears to us a proper definition, but 'photographic art' is a term as little applicable to the thing as if we said the *art of perspective* for painting, or *grammatical art* for poetry.

"Photographic science proceeds from chemistry. It is one of its most interesting off-shoots. The chemist has placed in the hands of the artist and amateur an instrument which dispenses with the arduous studies of perspective and the mechanical labour of the crayon and the pencil. Reagents, processes for employing photographic substances, and instruments at the service of this employment form the body of this new and delicate science.

"As to photographic art, we are of opinion that it has not a name, and we wish it were possible to give it one, which should express in one word the idea of art by the heliographic process. Art, generally, has for its object the external manifestation, by various means, of the thoughts, feelings, and passions of the individual. Whether these means be writing and grammar, perspective and the pencil, or even photography, the aim is the same. Only, photography, which is unquestionably scientific, executing at the same stroke the work of the crayon and of the geometrician, permits of the art taking a more elevated range.

"It has been stated, Monsieur le Ministre, that photography materializes art. This could only proceed from persons ignorant both of art and of photography. The artist who employs these processes of expression has as much freedom to select from nature as the draughtsman who employs his crayon. Besides, in art, the process is a secondary matter. It is the idea, the choice of the mode employed to express it, that is essential. We think that it is by their manner of understanding this important point that artists are divided into painters of style, and realists. The one believe that they may represent the object of expression crudely, just as it is; the others think that they must represent this object only as it seems most apt to render the special idea they have in view. It has been said, that the design produced by the sun belongs to the realistic genus, as it brings out parts useless to the general effect. Moreover, as the photographic process is at the command of everybody who can master a few preliminary details, they add, that this method of expression belongs rather to the province of manufacture than to that of art.

"Happily, Monsieur le Ministre, among the numerous productions of photography may be found many admirable ones which show what the true artist can derive from this new source. Can we refuse to accord the title of "works of art" to the landscapes of M. Bisson, the portraits of M. Salomon, M. Nadar, or M. Carjat, or to the "studies" of M. Aguado?

"For the landscape artist, the choice of position, the hour of the day, the study of the various planes; for the *genre* painter, or the portrait painter, the attitude, costume, accessories, choice of light—are not all these the resources of the artist who employs the new process as well as of him who handles only the crayon and the pencil?

"If these considerations, Monsieur le Ministre, appear to you sufficient to cause an end to be put to the confusion which hitherto has mistaken the means for the cause, the instrument for the thought which directs it, we take the liberty of praying you to grant a place for original works produced by photographic processes in the approaching Fine Art Exhibition, upon the same conditions as those required for painting, sculpture, engraving or lithography.

We have the honour to be, Monsieur le Ministre,

Your Excellency's very humble and obedient servants,

MEMBERS OF THE MARSEILLES PHOTOGRAPHIC SOCIETY."

THE SECRETARY remarked that the Society did not intend to enter upon a discussion on a subject upon which there are so many different opinions: viz., whether photography is or is not an art. It is an undeniable fact that we can produce an artistic work by photography. This is what the Marseilles Photographic Society maintains, no one up to the present time has denied this fact; there is, therefore, good and sufficient reason to claim for these works of art the rank and place they merit.

THE SECRETARY announced that the Marseilles Photographic Exhibition is fully organised, and that it will be opened to the public after as short delay as possible. The Society has not aimed at making so considerable an exhibition as the first. The progress accomplished during the year will be best shown by the results. Inspired by this idea, the committee has limited the space and the number of exhibitors. To have organised a new great exhibition really susceptible of offering a new interest, it was necessary for time to permit the photographic art to produce, invent, and perfect, and, especially, practically apply.

Dry processes and the carbon process have made but little progress during the past year. But in another year, certainly, we shall see productions possessing very great interest.

The course of lectures on practical photography will coincide with the exhibition. M. Leon Vidal, entrusted with this difficult task, is quite ready to commence it.

THE PRESIDENT reminded amateurs that the laboratory of the *Union des Arts* is now organised, and that they will find all the facilities necessary for the material part of their labours.

PHOTOGRAPHIC SOCIETY OF PHILADELPHIA.

THE stated monthly meeting for March was held in the rooms of the Society, on the evening of Wednesday, March 4, 1863. Vice-President FREDERICK GRAEF in the chair.

After the usual preliminary business, the following gentlemen were elected members of the Society, Felix D. Crane, Richard D. Petit, and John H. Simmons. Dr. Van Monckhoven was elected a corresponding member.

COLEMAN SELLERS, corresponding secretary, reported having received a letter from a gentleman of Boston, who had taken a prominent part in the investigation of the spirit photographs, in which he says, "I agree with you perfectly in supposing that the plate in the bath is changed during the time that the dark room is entirely without light, as is the case when the plate is removed from the bath."

The secretary, Mr. BROWNE, read a letter from a Mr. Cox, giving a description, illustrated by photographs, of a wheelbarrow dark tent; the pictures of it were examined with interest.

Mr. TAYLOR read a communication from Mr. F. A. Wenderoth (who was prevented from being present by indisposition), on the subject of enlargements by artificial light. He had made an arrangement of lime light in combination with a quarter size portrait tube, but had not been very successful in printing by development direct on paper; he had, therefore, turned his attention to enlargement on collodion films. He had made two negatives enlarged from ordinary transparent glass stereographs; one of a view in the Alps, the other of the town of Altoona, Pa. The negatives were exhibited, also prints from them; they measured 20 x 16 inches, and were not remarkably sharp, as the position from which they had been amplified had not been made with a view to enlargement. Mr. Wenderoth gave an account of his experience with the solar camera, and seemed inclined to favour the idea of enlarging on glass and then printing by superposition, as better in a commercial point of view than the use of the solar camera. In the specimens exhibited the exposure had been forty-five and sixty seconds with lime light. There was also exhibited developed prints made by Mr. Wenderoth five years ago, which were considered by him more permanent than the ordinary prints.

Mr. J. W. HURNE exhibited two card pictures with spirit accompaniment, which he had made himself. He said that his acquaintance with the spirit world had been so recent that he had not been able to prepare as many of these specimens as he should have liked. The spirit pictures were exactly like the ones made by Mmmler, but the photographs, as a whole, were far better than his; he had gone ahead of Mr. Mmmler in one respect, inasmuch as one of his spirits was head downwards, showing conclusively that it must have been taken in the act of descending to the earth. After many amusing comments on them by himself and others, he said that the spirits were from positives, the impression being made by lamp light in one or two seconds, the portrait of the sitter being made afterwards with the usual exposure.

Mr. BROWNE passed around for inspection some copies of engravings made by himself, which were much admired; the tone was black, but clear. He stated that the toning solution made use of was prepared as follows:—Gold solution, one grain to the drachm. Toning solution, 4 ounces of warm water, 2 draehms

of gold solution; neutralize with bicarbonate of soda, and add 25 grains of salt, 20 grains of acetate of soda, and 20 grains of nitrate of uranium.

The Harrison and Schnitzer globe lens being alluded to, Mr. BROWNE said he would refer to the testimony which had been given regarding their quickness in landscape work, but was sure they were very slow indeed for copying purposes. He had exposed an engraving in bright sunshine for two minutes, and had got a poor negative. He would be glad to hear the opinion of gentlemen present on the subject.

Mr. SELLERS had had too little time to experiment, but could state that he had seen copies made with the 12-inch focus globe in much less time than Mr. Browne gave; and that he had always thought that the 6-inch globe used by Mr. Browne must be quicker than the 12-inch, inasmuch as the rule of "the shorter the focus the quicker the work," the areas of work being the same in both cameras, holds good with these new lenses.

Mr. HUGH DAVIDS showed a negative made from an oil painting of a landscape, green being the prominent colour. He had made this with an 8-inch focus in ten seconds; engravings he had copied in even less time.

Mr. MORAN had been working a pair of the 2½-inch focus globes, and said that they had far exceeded his most sanguine expectations. He displayed a number of views made on the Wissahickon creek; in these he had used all the various sized openings, the largest being used to take some cattle in the foreground. They were remarkably good pictures, and called forth many expressions of admiration. His exposure with the large opening had been not over two seconds, but he thought he had over-exposed all, at another time he would shorten his time of exposure, he was hesitating in expressing his opinion that they were far from being slow workers.

Mr. TAYLOR stated that he had tried various samples of blue glass with a view to making a new skylight, and that by placing various shades of blue glass over sensitive paper, and exposing to the light, the paper would print slower in proportion to the depth of blue under all the glasses; and that the blue light falling on red and yellow paper, making the one purple and the other green, and a negative made of the colour, the purple and the green were less sensitive than the red or yellow; showing that the only effect of the blue is to shut out some valuable light, just as a curtain would do.

Here the meeting assumed a conversational tone, and the various pictures exhibited were examined with care. Mr. Gray added to the collection on the walls of the society room, two fine photographs—one from Rome, the other from England—the latter by Mr. Fenton.—*American Journal of Photography.*

Photographic Notes and Queries.

TRANSMITTED POSITIVES, &c.

DEAR SIR,—Perhaps the following may interest your readers. I was copying a lithograph the other day and wanted to make it very clean. I tried Mr. Osborne's clearing up process, and on pouring on pyro and silver, I *always* got a transmitted positive where the solution was poured on first, and I could produce as many positive spots as I chose by changing the place of pouring on repeatedly.

The following plan produced a very beautiful positive by reflection. A tannin plate was flooded with 3 grains of pyro without acid. No result was produced. I accidentally poured silver without acid into the pyro, and flooded the plate, and a magnificent clean positive resulted. I then stopped the development.

I have a mode of toning which I think is economical. I use acetate of soda, as given at the end of your 5th vol. and never throw away my bath. About ten minutes before use I put in the estimated quantity of gold for my prints, at six drops of a No. 8 grain to an ounce solution per quarter sheet of Rive. I do not neutralize and never hardly have meanness now, but I always use a preliminary acetate bath as recommended, and wash for some minutes in distilled water; before that, each print is put separately in the toning bath, and kept in motion, turning it frequently till the colour begins to change, *then, and not till then*, is it safe to leave it till toned. I fix in strong hypos. A bottle is filled one-third with the salt, and filled up with water, add a lump or two of chalk and use till the silver begins to be thrown down by light on the side of the bottle. When

this happens, I add a few drops of sulphuric acid to the hypos. Sun for two or three hours (of course the chalk must be out), and filter, neutralize with chalk, and filter again, and add more hypos to restore its strength. I send a specimen print.—Yours faithfully,
AN AMATEUR.

SIMPLE PLATE HOLDER.

SIR,—Having frequently noticed in the NEWS various suggestions for plate-holders, I trust you will allow me as an amateur to describe for the benefit of others a holder which I have contrived for my own use, for quarter and stereo plates, and which for portability, cleanliness, cheapness, and efficiency, I have found superior to anything I have been able to purchase.

It consists mainly of a small pair of ordinary pliers; round the nipping ends of these I tightly wind a few turns of string in order to prevent breakage or contact of metal with the plate as well as to give a better bite. Next I twist *tightly* round the handles an ordinary india-rubber ring, such as is used for binding papers, &c. This keeps the nippers firmly closed.

By inserting the two first fingers of the left hand between the handles a very slight effort is sufficient to open the blades widely enough to insert the plate.

Stereo plates are best held by the centre, as the leverage is otherwise too great to allow a firm hold. This plan too sacrifices less of the picture.

The whole costs me sixpence!—Yours obediently,

ARTHUR DALTON.

WEAK PRINTING BATHS.

SIR,—Should you deem the following communication worth notice, you are at liberty. I have been trying several experiments, lately, with different strengths of silver for floating paper. I find that with a weak solution I can produce a more brilliant print than with a strong one, providing a quantity of nitrate of soda be added. I operate as follows: Float five minutes on a solution, nitrate silver 20 grains, nitrate soda 60 grains, aqua 1 ounce; print rather deep and tone as usual. It will be noticed that they print rather redder and tone much quicker.

I enclose you three prints of one negative from one sheet of paper; No. 1 was done in the usual way, with a 70-grain solution of silver; No. 2 with a 20-grain solution of silver and 20-grains nitrate of soda; No. 3, silver solution 20 grains, nitrate soda 60 grains. You will see that a large proportion of nitrate of soda is necessary. I have not yet determined what proportion gives the best results; I will leave it to some experimenter who may have more time than I have.—I remain, Sir, yours, respectfully,
PUBBICOLO.

P.S.—I will send, in a few days, a recipe for a toning bath which I believe superior to any in use.

[The experiments of our correspondent seem to run parallel with those of Mr. Anthony recently recorded. Of the prints enclosed, No. 3 is about equal to No. 1, and both are superior to No. 2. Another print enclosed is marked as floated on a 5-grain silver bath, with 60 grains of nitrate of soda. It is somewhat mealy, which is ascribed to the over rapid toning induced, the effect having been produced by a 30 seconds immersion in the gold bath. We shall be glad to receive the toning recipe.—Ed.]

Talk in the Studio.

CONCERT IN AID OF A PHOTOGRAPHER.—Mr. John Watson, a photographer of old standing in the metropolis, well known to old photographers, has recently had the misfortune to become totally blind. A concert will be given on Monday evening next, at the Hanover Square Rooms, with a view to raising funds on his behalf. Those of our readers who would enjoy good music,—for a fine programme is provided,—and at the same time enjoy the "luxury of doing good," will do well to attend. The tickets are from half-a-crown to seven and sixpence each, to be had at the rooms and of various agents.

To Correspondents.

CONSTANT READER writes as follows:—"I am an artist at a photographic establishment (that is to say, I paint in oil and water colours in all its branches). I have a son, whom I have apprenticed to my employer at the same establishment. The indentures run that by the consent of his father, artist, he doth put himself apprentice to W. R. of C—, photo-

grapher, to learn his art, and with him after the manner of an apprentice to serve, &c. It then goes on in the usual printed form, that he shall serve his master faithfully, keep his secrets, and obey his lawful commands, &c., &c. At the close it states that the master shall teach, or cause to be instructed as a PHOTOGRAPHER the said apprentice. There is nothing about painting named in the indentures. When these indentures were signed I painted six days in the week, now I print three days only. My employer orders my boy, as his apprentice, to paint his photographs, and tells me and him that he can make him do so, and that he has a right to enforce it. Having laid the case before you, I beg to ask if you consider it as part of the duty of a photographer's apprentice to paint photographs. You will kindly be particular in this matter, as I have no doubt there are many similar cases." The question involved is a legal one, and will be decided by the construction of the phrasing in the indenture. Our opinion of the matter is, that painting portraits is no part whatever of a photographer's duty, or of his apprentice; and it is probable that the law will give the same decision.

W.—The brown colour of your prints appears to be the result of imperfect fixation. The hypo bath is either old or weak, or the prints have been stuck together whilst in the hypo bath. Probably in this case the latter, as the shape of one print is distinctly marked upon another, causing a stain and showing the contact. We suspect, moreover, that the toning, or fixing, or both, was conducted in the presence of some white light. We regret our inability to answer letters on difficulties of this kind by post, as such an undertaking would fully occupy our time. Such letters are not even read through when they arrive, but placed aside to receive attention on a day set apart for that duty in each week.

A.—The fact of the minute holes occurring always in one place, and near the end of the plate resting at the bottom of the silver bath, would suggest some turbidity in the bath, which rises for an inch or two upon the immersion of each plate. There are many causes of such pin-holes, but none that we know of by which the defects would be confined to one part of the plate always.

LUCIFER.—There are several good tents manufactured. We may especially mention Edward's Model Tent, by Rouch; and Smart's Tent, by Murray and Heath. How far they will be suitable for a tropical climate we cannot state. *A priori*, we should think a developing box, which does not envelope the head, would be most suitable.

X. Y. Z.—The best material for the window of a dark room is a suitable yellow glass. Where that is inconvenient, and a yellow blind only is required, Mr. Smart's silk is best; but if that be too expensive, two or three thicknesses of deep yellow calico, renewed whenever it fades, is the next best thing. It is a good plan to have one or two thicknesses of the yellow calico, and a thickness of yellow tannin. This does not fade, and it protects the calico.

W. W. H. WARNER, of Ross, requests us to explain that some delay in executing orders in hand for the profession may arise from some alterations, and the construction of a hot-water apparatus in his printing-house.

TYRO.—We do not know the gentleman you name. We do not consider £2 weekly too high a salary for a competent photographic printer in the country. We shall be glad to receive the communication referred to.

CHARLES CONNOR.—We do not clearly understand the nature of the deposit to which you refer as forming on some portions of your negatives; nor does the print enlighten us. Is the deposit fog?

H. M. R.—We have never used iodoform for the purpose of rendering a horny collodion porous. 2. We have no data upon which to form an opinion as to the quantity to be used. 3. Agitating the collodion with bicarbonate of soda will produce the result, and has, in our hands, been successful. After agitation let it stand for a day or two, and then decant from the sediment.

SUBSCRIBER D's note is written so illegibly that we are by no means certain that we read it correctly. 1. Grape sugar may be obtained in various ways, and from various sources, from grapes dried and fresh, from honey, from starch, &c. Neutralise the expressed juice of the grape with chalk, strain, add a little white of egg, boil, and evaporate until the sp. gr. is 1.32. Then allow to cool, the result is grape sugar or glucose in a solid mass. For details of other methods of preparing it, see any work on organic chemistry. 2. We have in use a gold toning bath which has been made for weeks, which shows no signs of the precipitation you deem inevitable. When the solution of chloride of gold is neutral, it is, however, very easily decomposed. We have repeatedly given formulae for gold solutions which will keep without decomposition. The gold precipitated from such solutions, by means of sulphate of iron, is in the form of a dark powder. It may be converted into chloride of gold by nitro-hydrochloric acid in the usual way. It is scarcely fair to bring papers before societies for the purpose of advertising secret preparations. It is also against rule, although such things sometimes creep in before those concerned to repress them are aware. We never publish such papers. All photographers should be familiar with the decimal system of weights and measures, which is likely eventually to come into general use. As a rule, however, we translate them; when they appear without translation into familiar terms it is from oversight. A table giving the equivalent terms used in this country is given in our ALMANAC.

J. D. Z.—The suitability of a quarter-plate lens for enlarging, and the extent of its powers, depends much upon its construction; quarter-plate lenses by different makers vary, so you can only learn by experiment the capabilities of your own. Mr. McNab, in referring to reversing the lens, simply means that the end usually towards the sitter should, in enlarging, be towards the sensitive plate. A Dallmeyer's No. 1 triple is peculiarly well suited for enlarging. We cannot say exactly the extent of amplification which may be secured without loss of definition; much will depend on the original to be enlarged, and much on the manipulation; but we have seen a card picture enlarged to a whole sheet of paper with excellent results. In copying an albumenized print you must be careful that no light is reflected from its glazed surface, or a deposit will be the result. You can only ascertain by experiment in your own studio the best mode of placing it to avoid such reflections. The defect in the paper is from bubbles in albumenizing.

PHILIP CRELIN, JUN.—Your pictures in the room are a little under-exposed. The definition is more or less faulty in all, apparently from the imperfection of the lens, but, possibly, from want of careful manipulation.

W. S.—We like the pictures received much. We will examine them more in

detail in our next. We will forward the card, asked for some time ago shortly.

M. P. R.—When a correspondent tells us he has carefully followed instructions and failed, with a process with which we and thousands of others have always succeeded, it is very difficult to give him a reason for his failure. We can only give the advice to try again more carefully, or change the materials. The print enclosed is certainly not toned at all, and, apparently, imperfectly fixed. The negative appears to be tolerably good. Such a stain might arise from various causes. Read the article on "Imperfect Fixation," in our last ALMANAC.

J. C. V.—Many authorities have condemned the use of methylated spirit for collodion. We think, without sufficient trial or good reason. We have used it for many years, without ever perceiving any bad result, either to the collodion or silver bath. The chief danger from its use is the possible presence of impurities in it. You must not use the "methylated finish," containing a certain amount of some resin that will, probably, make the collodion unstable, and, possibly, foggy. We see no reason why the presence of wood spirit, if pure, should be injurious.

N. 290.—It is quite possible to obtain good negatives with a bromo-iodized collodion and neutral bath. We frequently use both. 2. Of the three lenses by Dallmeyer, regarding which you inquire, each has its special use and value. For card portraits No. 2 B is best, if you have length of room. No. 1 gives very good pictures, but requires a smaller aperture to give the same definition, and is, consequently, not quite so rapid. The stereoscopic lens is of shorter focus still, and, of course, gives a smaller picture; but is excellent for stereoscopic purposes. No. 1 B will cover a larger extent with a larger aperture than the stereoscopic, and is, therefore, practically more rapid. The No. 2 B will, of course, cover a larger plate still. How large we cannot certainly say; probably about 6x5.

A. C. P.—In our own experience, that which you mention as being "very highly spoken of," you are somewhat in error as to the standing of the respective persons; but we cannot discuss the matter here. We can explain more when we see you.

A.—We have no faith whatever in the statement made. We have recently had a report from a very able photographer, giving a totally different account. The results were said to be very unsatisfactory. A report on such a subject will always, of course, be influenced by the taste or appreciative powers of the reporter. Some people are satisfied with very little, and quite charmed with mediocrity.

W. H. SIMONS.—We cannot tell you certainly whether the engravings in the illustrated journal in question are copyright or not. We should presume they are. And, what is still more probable, they may be copies of copyright photographs which are engraved by permission; in which case you would be infringing the law by copying them. You will run great risk of breaking the law of the land, and will certainly infringe the moral law if you make copies without ascertaining absolutely that no personal property exists in the pictures.

A. R. P.—The best remedy for loosening of the film consists in using perfectly clean plates, an adherent collodion, a nitrate bath not too acid, and in careful manipulation. In asking the number of prints a given quantity of hyposulphite will fix, you omit the most important element in the calculation, namely, the size of the prints. Read the article on "Fixing" in our last ALMANAC. A toning bath made with acetate of soda may be used over and over until it is exhausted. There is no difficulty in obtaining grey tones with it. If there be the slightest acid reaction neutralize with carbonate of lime.

YELLOW GLASS.—Two samples of glass have been sent by A. L. for examination in the spectroscopie. They are prepared with gelatine and nitrate of silver, and when viewed by transmitted light, have a dark reddish brown, translucent appearance. In the spectroscopie, however, they are seen to transmit red, yellow, and green rays up to the blue, and arc, therefore, unfit for employment in the windows of the dark-room. A piece of orange oiled-silk sent has the same faults as the above, but in a less degree.

G. C. C.—The dissolving, partial or entire, of the image in varnishing may proceed from two or three causes, some of which were discussed at the last meeting of the London Photographic Society, reported in our pages for April 10th. In your case it appears to have arisen from a certain condition of the collodion and the highly rectified spirit of which the varnish is made. Old collodion, or collodion made from gum-cotton produced at a high temperature, is most liable to this accident, being, to some extent, soluble in strong alcohol. The remedy consists in firstly allowing the varnish to stand for a few days without cork or stopper in a moist atmosphere, so that it may imbibe a little water. Adding a weaker spirit, or a drop or two of water, might answer, but would leave the varnish turbid for a time. Also taking care to use the least possible heat in varnishing, as heat aids the solution. Finally avoiding the use of the same varnish with the same collodion. Negatives suspected of the tendency may be safely varnished with a benzole varnish or a chloroform varnish, but not with a spirit varnish. The benzoin or amber varnishes may be used.

J. INSKIP.—We are obliged by your communication, and will make use of it in our next.

Several correspondents in our next.

IRON INTENSIFIERS.

ONE of the few disadvantages attending iron development is the frequent necessity for after intensifying with pyrogallic acid and silver, or some other preparation. Thus, not only two operations have to be gone through with careful washing between, but two solutions have to be kept prepared. Where rapidity of operations is of importance, as in large portrait establishments, or where rapidly changing aspects of nature are to be secured by instantaneous photography, the delay involved is a serious inconvenience.

Pending the success of the various experiments for securing sufficient intensity with an iron salt by the single operation of development, a method of intensifying with iron instead of pyrogallic acid will often be found of the greatest value. On another page we publish a communication from Mr. V. Blanchard to the final suggestion of which we call especial attention. It refers to the use of a weak iron solution with excess of citric acid in place of the usual pyrogallic solution for intensifying.

We have, during the last few months, been trying this preparation, and with unvarying success. Made in the proportion mentioned by Mr. Blanchard—five grains of iron, with ten grains of citric acid, in one ounce of water—it permits the addition of silver freely, and even when placed in the sunlight does not decompose. It intensifies the image readily, either before or after fixing, without the slightest tendency to fog the shadows. If used before fixing, it may be applied to the plate after the ordinary iron developer, without washing, which is so imperatively necessary with pyrogallic acid, and in such case it develops us well as intensifies, really bringing up detail not before apparent. In field operations, thus dispensing with present washing or future intensifying is of great advantage, and Mr. Blanchard has thoroughly tested its value in all his instantaneous work, during the last summer. The solution may be kept prepared for an indefinite time, and appears to improve with age. The proportions stated are not arbitrary, but have been found most generally useful as stated. The citric acid may, in cold weather, be reduced to the same quantity as the iron, or even less. Mr. Mainwaring, at the last meeting of the North London Society, showed a print from a rapid plate, which had been intensified with five grains of iron and five of citric acid. Tartaric acid may be substituted for citric acid, and we have recently found it quite possible, where rapid and vigorous intensifying was necessary, on a phantom image, to use a fifteen-grain iron solution, with three grains of tartaric acid, and to add silver freely, without any sign of decomposition, until after sufficient intensity was obtained.

We have recently been making experiments with other iron developers, for obtaining sufficient intensity at one operation. We do not like to speak with certainty upon the results of a few experiments; but hitherto we have obtained the best results with the saccharo-sulphate, great intensity,

with clean shadows and delicate gradation, being obtained by the simple process of development.

We have tried the formulæ of M. Renet with tartaric acid recently given in the letter of our Paris correspondent. Used as there stated, we find that a considerably increased exposure is necessary, the amount of citric acid being considerably in excess of what is necessary. The negatives develop very slowly, but are exceedingly delicate and clean. Probably one-third of the amount of acid would yield more satisfactory results.

IMPROVED SOLAR CAMERA.

WE have received from Mr. Stuart, of Glasgow, a couple of enlarged prints, in illustration of the powers of his improved solar camera. In order to enable us to judge more correctly of the results, they are from the same negative from which one of the prints we noticed some months ago was produced. With the solar camera in its old form, an exposure of two hours in continuous sunlight was necessary to complete the printing. The print before us was completed in one hour of sunlight, during which, however, there were three or four interruptions from the withdrawal of the sun. The negative had, moreover, from standing all this winter unvarnished, become brown and tarnished, and thus less rapid in printing. The prints are as sharp as we could desire, and beautifully modelled. The greatly increased rapidity of printing being obtained without any sacrifice of results.

We hope shortly to publish a detailed account of the improved apparatus; but we may remark in the mean time, that the accession of rapidity is largely due to the entire discarding of the mirror, and securing the necessary movements for obtaining the direct and continuous action of the sun through the condenser without displacement or interruption.

NEUTRALIZING THE TONING BATH.

ONE of the difficulties in preparing the alkaline gold toning bath arises out of the varying amount of acidity in different samples of chloride of gold. This renders it impossible to prescribe a definite proportion of carbonate of soda as the right amount to neutralize the acid present. And as excess of acid produces mealiness in toning, and excess of alkali frequently prevents toning altogether, it happens that where carbonate of soda is used, the most variable and unsatisfactory results are produced. Where the neutral salts of soda are added, more complex reactions follow, the hydrochloric acid is neutralized, but the weaker acid, in combination with the soda, is set free and remains in the solution. The toning is more regular and satisfactory, but unless the print be well washed before fixing, there is some danger that the traces of acid in the print may decompose the hyposulphite solution and thus, by liberating sulphur, peril the permanency of the print.

We have frequently felt it desirable to immerse the prints in a dilute solution of carbonate of soda between the operations of toning and fixing. This method, although effectual, is somewhat troublesome as involving one extra operation.

A better plan consists in neutralizing the free acid in the gold bath by means of carbonate of lime or common chalk in powder. Where a soluble alkali is used, it is of course easy to get an excess in solution; the carbonate of lime being insoluble, or nearly so, in water, neutralizes any free acid by its presence, whilst merely in a fine state of subdivision suspended in the solution, the precipitate being easily removed by subsidence or filtration, whilst excess in solution is impossible. This has before been generally recommended, in formulae in connection with chloride of lime; but there is no reason why it should not be used together with acetate of soda and similar salts. Mr. Frank Eliot, well known to many photographers as a skilful and intelligent printer, informs us that he uses in this way with the most complete success.

PRACTICAL NOTES ON THE NEW FIXING AGENTS.

BY G. WILKINSON SIMPSON.*

The practical results of the new fixing agents have been, in my hands, decidedly satisfactory. It is scarcely necessary to say more than this to obtain for the subject some interest and attention. It is unnecessary to dwell upon the importance of the questions involved: perhaps at no previous time were photographers so thoroughly alive to the subject. Much has been eloquently spoken and written of late years on the primary importance of good printing, and still more has been written and said, despondingly, of the imperfection of a process which depended upon hyposulphite of soda as a fixing agent. Not that good and permanent prints were not frequently produced by its aid; but that it was uncertain, was the complaint. It often "paltered with us in a double sense," and destroyed our reliance upon it. Its instability and treachery were its faults.

When a substitute for hyposulphite of soda for fixing prints, and for cyanide of potassium for fixing negatives, possessing many of the good qualities of both, and free from many of the faults of either, was suggested by M. Meynier, I, in common with many others looked for further information on the subject with considerable interest. And when the Committee appointed by the Photographic Society of Marseilles, to examine and report upon the subject, rendered an unfavourable account of the matter, stating, that the whites of albumenized prints became somewhat yellow under the action of the sulpho-cyanide of ammonium, I felt a good deal of disappointment. The committee appointed by the Photographic Society of Paris reported more favourably, but from their report there appeared to be some drawbacks to its use, such as the necessity of using a second bath of the salt to remove all traces of the compound formed by the action of the first.

In my hands the results seem to have been more satisfactory than those recorded in the reports referred to. Whether from some difference in the sample of the salt used, or from some other unnoted conditions, I do not undertake to determine; but the fact is so, that in my experiments, I have not met with some of the difficulties before recorded, as the results I will show you and the details I shall state will illustrate.

My only purpose in these brief notes is to refer to the practical results of a few experiments I have tried, recording my experience, where it differs from that of some eminent authorities who have written on the subject, with some hesitation and diffidence. The subject is, however, a new one; recognized authorities differ in the properties they ascribe to the sulpho-cyanides. The question for photographers must

be settled practically, and for this reason I record the facts I have observed. The theory of the subject I do not enter into at all. On that, something is probably still to be learned; in the meantime I commend attention to the interesting article on the subject by MM. Davanne and Girard, which will doubtless be published in all the journals.

I may premise the account of my results by referring to the advantages claimed for the sulpho-cyanides over the hyposulphites as fixing agents for positive prints. The sulpho-cyanides are more stable, not being easily decomposed so as to yield free sulphur or sulphuretted compounds, no part of the manipulation or materials used in positive printing having any tendency to liberate sulphur. Exactly the opposite facts to these are, as we know, true of the hyposulphites used. The salt formed by the reaction with silver salts and the sulpho-cyanides is readily soluble in excess of the latter, not forming at any stage a salt insoluble in the sulpho-cyanide solution. With hyposulphite, as we know, the opposite fact is true, as the perpetual stains from touching the unfixed print with fingers which have been in contact with hyposulphite, and from imperfect fixation, too abundantly prove. With the sulpho-cyanides the photographer is freed from this trouble, the sulpho-cyanide of silver formed by the reaction between nitrate of silver or chloride of silver and an alkaline sulpho-cyanide being readily soluble, even after exposure to light, in the latter. The sulpho-cyanide of ammonium is said to be a more perfect solvent for what is termed the albuminate of silver than hyposulphite of soda. The sulpho-cyanide is much more readily removed by washing from the print than the hyposulphite. There are some other advantages, but these are of the chief importance to the photographer.

I have used the term sulpho-cyanides in the plural because I have tried two: the sulpho-cyanide of ammonium and the sulpho-cyanide of potassium. The other sulpho-cyanides have not, I believe, been tried for photographic purposes.

The sulpho-cyanide of ammonium I have used, is, I believe, a very pure sample, prepared by Messrs. Hopkins and Williamus. I used a solution containing one part of the salt in three of water. An albumenized print a little more over-exposed and over-toned than for hyposulphite fixing, as I had been led, from the record of other experiments, to believe would be necessary, was immersed in the sulpho-cyanide solution. The results which followed were in all respects, so far as the eye could perceive, similar to those with a strong solution of fresh hyposulphite of soda, but the changes were a little more rapid. The print first turned very red and gradually resumed, in the course of a few minutes, its original purple tone. I left it for a quarter of an hour, or thereabouts, and then washed carefully. The resulting print was too dark and too black. The action of the sulpho-cyanide had not been to reduce the depth or the colour as I had anticipated.

I then printed some others just the depth, and toned to just the colour, I should have done for hypo fixing, and treated them with the sulpho-cyanide in the mode just described, and with some variations to be referred to. Some of the prints I now produce, and I think you will agree with me that they are as good in tone, as pure in the whites, and as brilliant generally, if not better, than the hypo-fixed print produced at the same time, from the same negative, and with similar conditions in all respects, except in the fixing. I found no trace whatever of the yellowness of the whites described by the Marseilles Committee, until I introduced other conditions which I shall describe presently. Some of the prints are, as you will perceive, on ordinary albumenized paper, and some on the albumenized enamelled paper recently introduced. I did not find in any case the slightest loss of tone produced by fixing.

I next tried the sulpho-cyanide of potassium, a sample forwarded to me for trial by Messrs. Bailey and Son, of Wolverhampton. After one or two tentative experiments, I made a solution containing one part of the sulpho-cyanide of potassium in two parts of water, and proceeded as described

* Read at a Meeting of the North London Photographic Association, April 22.

with the sulpho-cyanide of ammonium. The result was in many respects similar, with these differences: that the depth appeared a little less reduced and the colour a little more. The depth appeared to be less reduced than with new hyposulphite; the colour was a little more reddened than with the sulpho-cyanide of ammonium, but the loss of colour was not greater than often occurs with new hypo. In some of the prints I fancied there was greater brilliancy when the sulpho-cyanide of ammonium was used than when the potassium base was present; but in others I felt doubtful. Whether the difference in the results was actually due to the different bases present, or was due to the especial samples used, I cannot say. The sulpho-cyanide of potassium, it is perhaps necessary to say, appears to possess little more than half the energy of sulpho-cyanide of ammonium as a solvent of salts of silver.

In none of the cases where the solutions used were of the strength indicated was the slightest yellowness in the whites apparent. I did, however, contrive to get it. After fixing several prints in a small quantity of sulpho-cyanide of ammonium, and allowing the solution to stand for a day or two in an open vessel, a toned print was immersed in it, which immediately assumed a bright yellow tint, approaching orange. The print, when submitted, however, to a fresh solution, one part in three gradually resumed its proper tint, the lights becoming perfectly white and pure. On another occasion I essayed to fix a print in a solution of sulpho-cyanide of potassium, one part of the salt in five of water. The result was that the print assumed a deep orange tint at once. It did not occur to me then to try a stronger solution, and the print was thrown away as a failure. Whether this result will occur on all occasions where weak or exhausted solutions are used, I am uncertain. I have only tried it twice, and with those results. What is the exact nature of the decomposition I am uncertain, but it is probable that the yellow colour is due to sulpho-cyanogen.

There is another point on which I found my experience with that of some of the French authorities. We are told that on immersing the print in the fixing bath it becomes covered with a white veil of sulpho-cyanide of silver, and also that on first immersing the print in the washing water the latter becomes turbid, the result of a decomposition of the double sulpho-cyanide of ammonium and silver, effected by the water; and that for these causes the print requires removing to a second fresh bath of the fixing agent, of the same strength as the first, in order to remove the traces of sulpho-cyanide of silver left in the print. So far as I have been able by careful observation to perceive, I have not met with those results, although there appears every theoretical reason that they should take place*. The only changes I have seen in the print whilst in the fixing solution are those I have described as resembling the changes produced by hypo. The print first reddens and then resumes the tone it acquired in the gold bath, without any appearance of a veil. On immersing the prints fresh from the sulpho-cyanide solution in a limited quantity of washing water I could perceive no turbidity except in the cases where a weak or exhausted solution was used for fixing. Some of the prints, however, I immersed, as directed, in a second fresh fixing bath. I have not, as yet, been able to detect any difference in the results where this precaution is taken.

* The reactions which take place are thus stated: On immersing the print in a sulpho-cyanide solution, the sulpho-cyanide of silver is formed, which is dissolved again by the excess of sulpho-cyanide of ammonium, and a double sulpho-cyanide of ammonium and silver is the result. This double salt is not soluble in water, but is decomposed by it into sulpho-cyanide of ammonium, and sulpho-cyanide of silver; the former being dissolved in the water. The latter, being insoluble in water, is left, to some extent, in the print. Hence the apparent necessity for successive baths of sulpho-cyanide of ammonium to remove, as far as possible, all traces of sulpho-cyanide of silver from the print. Experience alone will determine the extent to which these successive baths are necessary. We have now some prints fixed as described, and, probably, containing some traces of sulpho-cyanide of silver, placed in strong sunlight to see if any darkening is the result. One print was merely rinsed in one or two changes of water, after leaving the sulpho-cyanide of ammonium; neither this nor the others have as yet, after several days' exposure, shown any change.

The salts are extremely soluble, and the washing appears to be very easily effected. As the per-salts of iron are a most perfect and delicate test for the presence of a sulpho-cyanide, by striking a blood-red colour, it will be easy to ascertain when they are effectually removed from the print by washing.

I may state that all the comparative experiments were conducted under, as nearly as possible, the same conditions. The paper was excited on a neutral, and somewhat weak, silver bath, containing about fifty grains to the ounce of water; the toning by an acetate of soda and chloride of gold bath made some weeks ago.

Regarding the permanency of the prints, we cannot, of course, as yet speak with certainty; we can only rest satisfied that we have secured some better conditions of permanency. On one point, I must confess that I feel considerable disappointment. I refer to the presence, in the fixed prints, of traces of silver in the whites, just in the same degree as in hypo-fixed prints. From the experiments of my friend, Mr. Spiller, and the opinion of some of the French authorities, I had been led to hope that the sulpho-cyanide of ammonium was a perfect solvent for the compound formed between nitrate of silver and albumen. Mr. Spiller's experiments consisted, however, in submitting the hypo-fixed prints, after perfect washing, to a concentrated bath of sulpho-cyanide of ammonium. This, he found, removed the traces of silver remaining, in combination with the albumen, in the whites. In my own hands, the prints fixed as described, washed, and dried, exhibit the characteristic brown stain, indicating the presence of silver, when sulphide of ammonium is applied to the whites, and in just about the same degree as hypo-fixed prints. All the prints I have tried give this result; whether treated with the ammonium or potassium salt; whether submitted to the action of a second fixing solution or not; and whether immersed a few minutes or a few hours.

As a fixing agent for negatives I have not tried these salts to any great extent. In the degree of concentration I have mentioned, namely, one part of the salt in three of water, they dissolve the iodide of silver very slowly; too slowly for use by pouring on to the plate, as the process would be most tedious. If used as a bath for immersing the plate, I have reason to believe that the solution will lose much of its energy by standing in an open vessel. The only mode of using it for negatives with advantage appears to consist in the employment of a very concentrated solution.

In regard to the poisonous character of this salt some doubt seems to exist. Various authorities state that hydro-sulphocyanic acid has a similar poisonous action to hydro-cyanic acid, and we would naturally infer that the sulpho-cyanides possess a poisonous action similar to the cyanides. M. Meynier says they do not, and Fownes, regarded as a careful writer in this country, makes a similar remark. The only evidence I have on the subject was a painful irritation set up by the action of the solution on a scratched finger.

In the course of various experiments not necessary to detail here, I met with one result which appears to contradict very distinctly the opinion of various authorities. Grotthuss, for instance, a German chemist, says that "sulpho-cyanide of silver blackens by exposure to light even more quickly than the chloride," a fact which, if true, would be of considerable interest to photographers. Other authorities make similar statements. I precipitated a quantity of sulpho-cyanide of silver by the decomposition of sulpho-cyanide of ammonium and nitrate of silver, and exposed it to diffused light for a day without any change or blackening taking place. Thinking that it was possible that the presence of free nitrate of silver might assist blackening I added some nitrate solution to the sulpho-cyanide. It has now stood for two days more in diffused light without any change, as you may perceive from the sample I now pro-

duce.* This is very readily soluble in excess of sulphocyanide of ammonium.

The question of price becomes finally an important consideration. On that subject I am afraid that I cannot at present give any very satisfactory information. As at present manufactured there does not appear any chance of the sulpho-cyanide of ammonium becoming a cheap salt. The price of that I have been experimenting with is four shillings an ounce, and of the sulpho-cyanide of potassium one shilling an ounce. Mr. Williams hopes, by some improvements in the method of producing it and increased demand, to be able to offer the former at half that price, or possibly, ultimately, a little lower than that; but so far as present evidence exists, it is impossible to state that it will ever become very cheap. Its purity is very important, and one of the most common impurities is a polysulphide of ammonium, which would be most fatal to the print. There is some hope, as stated by the French authorities, of producing it from gas residues, and Mr. Williams informs me that he has some on hand for that purpose; but even with this we fear that the cost of production, rather than of the materials, will be considerable. It is to be remembered, however, that when hypo sulphite of soda was first used in photography it cost three shillings and sixpence an ounce, and that even sometime after it was regularly used by professional photographers it cost a guinea a pound. Remembering these facts we may hope that if the new salts prove as satisfactory as we hope when further tested, they will soon be produced at a price which will be no barrier to their regular employment, and thus, possibly, introduce the era of permanent photographs.

ON THE DEVELOPMENT AND INTENSIFICATION OF THE NEGATIVE IMAGE.

BY VALENTINE BLANCHARD.

So much has already been said on this subject by those qualified to speak with authority, that it may appear superfluous, at first glance, to write further on a theme apparently exhausted. As, however, there is much in the individual experience of each experimentalist, that appears to clash with many of the preconceived notions, and as little points of detail are all important in the practice of the photographic art, I may be pardoned if much of what is here written prove simply a twice told tale.

Common place as appear the operations involved in the development of the negative image to those constantly engaged in the production of photographic pictures, there is no point in the whole photographic process where greater variety of results can be produced.

The employment of salts of iron in place of pyrogallie acid, has completely changed the character of the negatives. Instead of pictures of great depth, but lacking detail, we now have great softness in our pictures, but with it frequently a want of vigour. The great aim should be to combine the depth of the pyrogallie negative with the softness and detail produced by the iron salts. This is completely gained by most of the first class operators, but a great many of the pictures we see show a decided want in this respect.

It will be found that the cleanest pictures are produced by weak solutions of iron, and moderately large proportions of acetic acid, but the exposure is longer. A solution of 10 grains of iron and 20 drops of acetic acid to the ounce of water will give, with a 30-grain silver bath, negatives, which, while they develop slowly, yield prints of great roundness. With such proportions a moderately experienced operator can ensure wonderfully uniform results, as, in consequence of the slow development of the image, the employment of only ordinary care will produce clean pictures. It will be found also, that with the employment of a weak bath and the developer above mentioned, a considerable amount of

diffused white light may find its way into the supposed dark room, or in at the lens, without absolutely spoiling the negative, but with highly bromo-iodized collodions and with the bath and developer considerably increased in strength, the *slightest* trace of white light either in the room or lens, will very materially mar the beauty of the negative. The insidious influence of the light is so slowly felt, that the operator may easily be led to blame anything but the right cause. The unfortunate collodion or bath most frequently comes in for the blame. But where all these points are carefully attended to it will be found, that with a bath nearly neutral, of 35 or 40 grains, with a developer of iron 30 grains, acetic acid 15 minims, negatives of great beauty and depth can be produced, with an exposure altogether insufficient where weaker solutions are used, and, in many cases, these negatives will be found sufficiently dense, without any after method of intensification.

It may seem unnecessary to mention the importance of keeping out white light, but it is so easy to get into a jog-trot method of working, and make up the deficiency by some after process. A few days ago I was in the room of a friend who produces some really good pictures; I however found fault with the quantity of silver piled upon the image in many of his negatives. He replied that unless he did so the prints looked flat and wanting in brilliancy, and that the public found fault with them. On going into his dark room I was shocked at the amount of white light he permitted to enter. He, however, said it did not make any difference in his results. But I am satisfied, from the appearance of his negatives, that by stopping all the white light out he would get negatives that would print in half the time and be equally brilliant. Of course, if a negative very slightly veiled in the shadows be produced, it is so very easy, by a liberal use of silver in intensifying, to make up for it. But how much better to do away with the necessity for such a waste.

Very vigorous negatives can be produced by the employment of an extemporaneous acetate of ammonia in the developer. My method of operation is as follows: Of the iron 4 drachms are dissolved in 16 ounces of water, and into 4 drachms of acetic acid 1 drachm of liquor ammonia is poured. Violent effervescence ensues. As soon as this is over it is poured into the iron solution. With this developer I frequently secure negatives that require no after intensification.

It will be found of great service if a quantity of iron solution be made, but without adding the full quantity of acetic acid. Then pour out for the day's supply as much as may be needed, adding the acid to make up the deficiency, that is to say, if a developer containing 15 minims of acetic acid to the ounce be in use, add half only of the acid when the stock of, say a Winchester quart, is made. Then, if a pint be needed for the day's supply, 2½ drachms of acetic acid must be added before use. The acetic acid, when added in this manner, will be found to check the energy of the iron more completely, and enable the operator to produce cleaner negatives. It is a good plan also to make concentrated solutions of iron of known strength, and weaken at the time of use, adding the extra acid as above described. It will be found that while a strong solution is undoubtedly difficult to use, yet when skilfully poured over the plate negatives can be produced that need but little intensification.

Some time ago I advocated for intensifying the use of a solution of iodine, followed by pyrogallie acid and silver when needed after fixing. I have, however, found in practice that its use is dangerous, for frequently when large numbers are printed from the negative, it gradually blackens under the influence of the light, indeed to such a degree as to render negatives that were soft and harmonious when produced perfectly useless after six months' use. The same results have been noticed by Mr. Hughes, Mr. Williams, and others, when the bi-chloride of mercury, followed by iodide of potassium, has been employed. It would be desirable, if a preparation of iron could be employed as a developer,

* This sample, after standing several days in diffused light, without change, was placed in direct sunlight, when, in a few hours, it changed to a pale lavender tint, and has not gone further since.

which would permit the addition of silver when necessary without rapid decomposition. I have tried the addition of small quantities of glycerine and honey to the developer with varying success. If the bath contain no nitric acid, but a drop or two of acetic acid instead, it will be possible to employ a developer containing honey and glycerine, into which silver can be freely dropped. But at present I have not been able to employ it with uniform success. As, however, experiment in this direction is important, for there is nothing so beautiful as the negative developed completely with iron.

The nearest approach to this desired result is gained by the employment of a re-developer of iron, containing a liberal quantity of citric acid, say iron 5 grains, citric acid 10 grains. This solution, unlike pyrogallic acid, improves with age. Where a new bath is in use, as in instantaneous operations out of doors, and no alcohol is needed in consequence in the developer, the employment of this solution will effect a great saving in water, for no washing will be needed between the two operations. As soon as the image is developed by the ordinary iron solution, the image is washed, *if necessary*, or not, at pleasure, and then a portion of the re-developer is taken, and silver dropped in *ad libitum*. This is poured on and off until the requisite density is obtained. It will be found that the deposit is more delicate than that produced by pyro and silver. The negative is now washed and fixed in the usual way. When taken out in the light the image will be found of silver whiteness, and easy to be seen by reflected light. Indeed, it will be found to possess many advantages over the pyrogallic intensifying solution.

PHOTOGRAPHIC CHEMICALS.

THEIR MANUFACTURE, ADULTERATION, AND ANALYSIS.

Silica—(continued.) The combinations of silica with the alkalis are of the highest importance to all engaged in photography, inasmuch as these bodies enter largely into the composition of glass. The chemistry of the alkaline silicates is most complicated, and would be of very little interest to any of our readers, who would, doubtless, never desire to make their own glass, however perfectly our instructions for that purpose might be given. There is, however, a class of silicates which possesses interest in another direction. We allude to *soluble glass*, which, from its nature, is likely some day to be used extensively in photography. This product was first minutely examined by Fuchs. To obtain a good result, take fifteen parts of powdered quartz and ignite them with ten parts of crude potash and one of charcoal (which decomposes and expels the sulphuric acid contained in the potash), till perfect nitrification takes place. A good red-heat will be required for this purpose. The mixture must be put in a good Hessian crucible, not more than half filled, and the lid placed firmly on. The crucible is then to be put in a wind-furnace, if obtainable, or in a common fire, with a *blower* on, and exposed to a powerful heat from coke, until, on removing the lid, the contents are seen to be perfectly fused. The hard, blistered, greyish-black glass thus obtained is pulverised in a mortar, placed in a flask, and covered with its own weight of water. Heat is applied, and after half an hour, four more times its weight of water are to be added, and the whole boiled together for four or five hours. It will, if the operation has been successfully conducted, almost entirely dissolve in this time, leaving only a residue of impurities, carbonaceous matter, &c. Now filter the solution, and evaporate the clear liquid to a syrupy consistency. By simply drying the solution, the soluble glass is obtained colourless, transparent, and brittle, with a conchoidal, vitreous fracture, but softer than glass. It has a slightly alkaline taste and reaction, and after thorough drying still contains twelve per cent. of water. It is permanent in the air, does not absorb car-

bonic acid from it, and effloresces only when accidentally mixed with other salts of potash. In the fire it swells up from loss of water, then fuses, and forms an hydrous soluble glass. Dilute acids decompose it, with separation of silica, more easily than concentrated acids. It dissolves very slowly in cold, but readily in boiling, water, when in solution of a syrupy consistency, as obtained by the evaporation of the original liquid, soluble glass forms a tenacious, somewhat turbid, treacly liquid. On boiling or exposure to the air, it becomes covered with a tough skin, which disappears when thrust beneath the surface. After evaporation at a high temperature, it becomes very tenacious, and may be drawn into threads like melted glass. It dries up to a varnish when spread upon wood, &c., and the combustibility of which it diminishes. A dilute solution absorbs carbonic acid from the air—a concentrated one scarcely at all. The stronger acids precipitate silica from the solution, as do also alkaline carbonates, and many ammoniacal salts. Phosphate of alumina, and carbonate, phosphate, or sulphate of lead, when rubbed up with a solution of soluble glass, yield a tenacious mass, which becomes as hard as stone, when exposed to the air. The above properties of solution of soluble glass point out its great value to photographers in many respects. As a varnish it would be perfect, were it not for some little difficulties which are scarcely overcome at present, and which interfere with the uniformity of the film. Several experiments upon the employment of soluble glass are given in detail in our back volumes.

Glass consists of a mixture of silicate of potash or soda, or of both, with one or more silicates insoluble in water, such as silicate of baryta, strontia, lime, magnesia, alumina, manganese, iron, and lead. Pure silicate of potash or soda, or a mixture of the two, even with a sufficient quantity of silica to form a very infusible glass, would still be attacked by water and acids. Silicate of lime is likewise acted on by acids; but a mixture of it with silicate of potash or soda resists their action.

Such mixtures of silicate of soda and potash with silicate of lime, &c., are more fusible than the simple salts, and require a smaller amount of silica to render them capable of resisting the action of water and of acids. They contain between two and three atoms of silica to one atom of base, and still less when alumina is also present. The glass is more infusible and offers greater resistance to the action of water and of acids, the larger the proportion of silica and alumina it contains; it is more easily fused and attacked by water and acids the greater the excess of potash, soda, baryta, lime, magnesia, or oxide of lead which it contains; an excess of the last mentioned oxide renders it particularly fusible, of a high specific gravity, soft, easily scratched, and corroded by acids. Lead glass is also highly refracting, and on this account is of great service in the manufacture of lenses.

When water stands in contact with glass for some time, it extracts potash or soda from it, together with a portion of silica, the decomposition taking place with greater ease in proportion as the glass is richer in these alkalis, and more minutely divided, and the temperature of the water higher. The powder filed from white glass reddens moistened turmeric paper. Water triturated with pounded glass in an agate mortar becomes alkaline, and on the addition of sal ammoniac deposits flakes of silica. Water becomes alkaline after long digestion with glass at a boiling heat, and likewise turbid from separation of an insoluble compound of silicic acid and lime. An alkaline reaction is also exhibited by the powder of bottle-glass. After sufficient washing, it no longer reddens turmeric paper, unless it be recrushed in an agate mortar. These effects are much more striking with some kinds of English glass than with foreign glass, in which potash is generally employed as the alkaline base. It is for this reason, amongst others, that foreign chemical glass apparatus is so highly prized in this country, and Florence flasks are so frequently recommended for experiments in which solution or digestion at a high temperature is to be effected. In common glass, even the

moisture in the atmosphere produces an injurious effect. To this is due the annoying appearance in lenses, occasionally even by our best makers, known as sweating, caused by the atmospheric moisture separating out the potash and soda, and standing on the surface in a fine dew consisting of globules of alkaline solution. The silica and lime are left behind on the surface of the glass, and in time this decomposition causes the surface to exhibit prismatic colours. Sometimes this superficial decomposition is scarcely visible, but on warming the glass, numerous fine scales peel off, and leave the surface dull and opaque.

The pearly stratum with which specimens of antique glass found buried in the earth are covered consists almost wholly of silica.

Most acids attack glass, the action varying with the strength of the acid, and also with the quality of the glass—alkali being dissolved from it. Solutions of potash and soda also decompose glass, dissolving out the silica with greater ease in proportion to their temperature and degree of concentration. In some common varieties of glass, even at ordinary temperatures, the action is so strong that the glass sometimes cracks to pieces. When lead is present in glass, it tarnishes very readily by exposure to sulphuretted hydrogen. The dense glass used for prisms and lenses requires preserving away from this gas with great care, as it is acted on and darkened on the surface even by the ordinary atmosphere of a dwelling-house.

ON THE INFLUENCE OF SULPHATE OF SILVER IN THE SENSITIZING NEGATIVE BATH.

SULPHATE of silver is often contained in nitrate of silver made with nitric acid containing sulphuric acid. The solution of such nitrate, therefore, contains a small quantity of sulphate of silver which imparts to the bath the property of furnishing films more sensitive than if the nitrate employed had been purer; it gives quicker and more sensitive negatives.

If the quantity of sulphuric acid be too great, the sensibility remains, but the negative is spoiled by short lines resembling the letters of the Turkish alphabet and the characters used in stenography. These lines become fully visible only upon developing, and are caused by the absence of iodide of silver upon their path.

If the nitrate contains a greater quantity, it remains on the filter, for the sulphate of silver is but slightly soluble.

Failures due to the presence of sulphate in the nitrate are very frequent with the nitrate obtained from the residues of paper, filters, &c., treated as they are too frequently directed in books on photography.

The mode of treating then indicated by many writers must necessarily furnish a nitrate as rich as possible in sulphate of silver; to be convinced of this, it is only necessary to examine the prescriptions.

The papers are burned and the ashes placed in contact with liver of sulphur; sulphide and sulphate of silver are formed. The residue washed, decanted, then dried, is roasted to transform the sulphide into the metal silver.

To the last residuum nitric acid is added, then diluted with water, to be filtered.

What passes through the filter is the nitrate in solution accompanied with sulphate which is found in exact proportion to the water added.

This water evaporated, generally gives a nitrate containing from 5 to 10 per cent. of sulphate of silver; a nitrate quite unsuitable for negative sensitizing baths.

It is supposed that the sulphate may be separated by crystallizing the nitrate, but it is not; the sulphate crystallizes also, or is so completely in contact with the crystals of nitrate, that there always remains sufficient to cause the lines described above.

Method of treating Spoiled Nitrate Baths.

Baths are often put aside upon pretexts more or less well-

grounded, and every one knows that a new bath is always better than a doubtful one.

In order to obtain new baths without great loss, the following process will furnish excellent nitrate without much difficulty:—

The spoiled bath is filtered into a flat dish, in which a piece of pure copper is placed. After a contact of two or three hours (according to the quantity of the bath and the size of the piece of copper), all the nitrate of silver contained in the bath is converted into silver in the form of powder. The contents of the dish are filtered, then the silver powder is washed with several quarts of water poured upon the filter; this powder being dried, it will serve to make nitrate, taking care to keep it in a state of fusion for several minutes, in order to convert any particles of copper present into insoluble oxide.

The silver is in a very finely divided state; it is best to pour the nitric acid upon it in small quantities only, so that its action, which is sudden, may not cause particles of silver to be thrown out of the crucible.—*Bulletin Belge.*

GENERAL STUDY OF PHOTOGRAPHIC POSITIVES.

BY MM. DAVANNE AND GIRARD.

CHAPTER V., ON FIXING (CONTINUED).

§ VI.—On the Employment of Sulpho-cyanide of Ammonium.

BESIDE the three substances previously proposed for fixing positives, cyanide of potassium, caustic ammonia, and hyposulphite of soda, another has been recently introduced—a salt hitherto rare but of which many circumstances combine to render the manufacture abundant and cheap. This salt, which M. Meynier, chemist, of St. Barnabas, near Marseilles, has proposed and described the qualities, is the sulpho-cyanide of ammonium, or sulpho-cyanhydrate of ammonium.

The examination of the properties which can recommend this substance in an economical point of view, necessarily find a place in our "General Study of Photographic Positives." In order to render this study profitable, and to allow a comparison to be made of the qualities and defects of the salt in question with those of other fixing agents, we follow in this part of our task, the same method as with hyposulphite of soda, ammonia, &c.

Properties of the Sulpho-cyanide of Ammonium.—This is a white salt, crystallizable, decomposable at high temperatures, and extremely soluble in water and in alcohol. Considered in reference to the decompositions it can undergo by the moist way, this salt exhibits very remarkable conditions of stability in a fixing point of view.

For the substances which photographers have most to fear, with regard to the fading of their pictures, are, as we have frequently observed, free sulphur, sulphuretted hydrogen, or the compounds susceptible of producing them. Now, chemistry informs us, and we have verified it by new researches, that the reducing agents alone—nascent hydrogen, acidulated protosulphate of iron, &c., are susceptible of disengaging, in the state of hydrosulphuric acid, the sulphur of the sulpho-cyanides, but none of these agents intervene in positive photography.

Doubtless, the sulpho-cyanides are not stable; left for a considerable time in contact with the atmosphere, they deposit a yellow powder, sulpho-cyanogen, the formula of which is not yet fully established, but which we may consider as a sulphide of cyanogen with sulphur in excess. On the other hand, the alkaline sulpho-cyanides, treated with the concentrated mineral acids, or by chlorine, leave a deposit, either of sulpho-cyanogen in powder, or persulpho-cyanhydric acid in fine yellow needles. But the compounds thus obtained are themselves exceedingly stable, and do not, under the conditions in which photographic fixing is effected, either separate sulphur in a free state, or in the state of sulphuretted hydrogen. As to the sulpho-cyanides, such

as the sulpho-cyanide of silver, they present a surprising stability; this substance may be boiled with nitric acid; even calcined with nitrate of potassa, and, in those circumstances, decomposes only after a very prolonged contact with those reagents. Thus, from our present point of view, the sulpho-cyanides present themselves at once under very favourable conditions: the dilute mineral acids, the concentrated organic acids, very concentrated nitrate of silver, solid even, can never cause with the sulpho-cyanides a disengagement of sulphur, or sulphuretted hydrogen comparable, with that produced by hyposulphite.

Action of the Fixing Salt upon the Picture.—This established, the first question that presents itself is the following:—Can the sulpho-cyanide of ammonium remove all the argentiferous compounds? We have no hesitation in replying in the affirmative. For a long time it has been known that the alkaline sulpho-cyanides dissolve the salts of silver; this fact is recorded in all treatises on chemistry; but experiment has shown us that its solvent faculty is more absolute than that of the hyposulphite.

The action of this salt upon nitrate and chloride of silver is more decided, as every one may ascertain for himself. Take a solution of nitrate of silver, and pour into it some drops of the alkaline sulpho-cyanide, a white precipitate of sulpho-cyanide of silver will appear: upon your adding an excess of the reagent, the precipitate will quickly disappear. Chloride of silver, shaken into a solution of sulpho-cyanide, is dissolved in the same manner.

The clearness of these two reactions admits of our passing them over rapidly; we therefore devoted all our attention to the solution of albuminate of silver. We recognized that the solution was complete, and that the action of the sulpho-cyanide was, from this point of view, more energetic even than that of hyposulphite of soda. For, on the one hand, we precipitated some albumen by nitrate of silver; then, after well washing the precipitate with distilled water, we treated several times, one portion with sulpho-cyanide of ammonium, the other with hyposulphite. Again, well washed, the precipitates were then calcined: that which had been treated with sulpho-cyanide furnished traces of silver only; while that treated with hyposulphite of soda furnished very notable quantities. On the other hand, we fixed, comparatively, by means of these two agents, some albumenized papers, which we afterwards burned; and, in this case, we recognize a difference of the same kind quite favourable to the employment of the sulpho-cyanide, but which, we must say, was less marked than in the first case.

The sulpho-cyanide then attacks albuminate of silver more energetically than hyposulphite of soda, and, consequently, it presents a decided superiority over the latter with respect to the absolute fixing of the whites of the proofs.

Next to this first question we place a second no less important. The sulpho-cyanide of ammonium, when employed under suitable conditions, leaves on the proof no portion of its substance capable of change, either immediately or ultimately. In that respect it behaves like fresh hyposulphite of soda, but like the latter, it exposes the proof to some risk in the case where the manipulations have not been conducted with the necessary care. These dangers consist, 1st, in the precipitation of a small quantity of sulpho-cyanogen, either in the case where, by accident, some concentrated acid is present at the moment of fixing, or in the case where the bath full of proofs is exposed to contact with the atmosphere for an extreme length of time. 2nd, in a feeble quantity of sulpho-cyanide of silver remaining in the proof in consequence of incomplete fixing. In the first case, the bath, becoming thick, deposits a yellow powder, and the proof is immediately stained: in the second case, the sulpho-cyanide of silver, sensitive to light, quickly blackens; in both cases the photographer is immediately aware of what takes place, an advantage he is far from possessing with hyposulphite of soda, the injurious effects of which are not immediately developed, and in this particular the purchaser has an excellent commercial guarantee.

Limit of Saturation of the Sulpho-cyanide of Ammonium.—The study of this part of the subject, so complex with regard to hyposulphite of soda, is very simple with the sulpho-cyanide. Upon contact with the salts of silver, whichever they be, the alkaline sulpho-cyanides give rise to a white precipitate absolutely insoluble in water, the sulpho-cyanide of silver corresponding to the formula C_2NS, AgS . This salt combines with the sulphocyanide of ammonium to yield a double salt.

$C_2NS, AgS + C_2NS, NH_4S$, uncrystallizable in water, which it decomposes; but crystallizing with facility in an excess of sulpho-cyanide of ammonium. Isomorphous with this latter, the double salt always acquires a certain quantity in crystallizing, and we are thus able to obtain salts varying according to their composition from

$2(C_2NS, AgS) + 3(C_2NS, NH_4S)$

to that corresponding with the formula,

$C_2NS, AgS + 6(C_2NS, NH_4S)$.

Between all these there exists no other difference of properties than the instantaneous decomposition of the first by water, opposed to the solubility of the latter in a very minimum quantity of water, a greater quantity of this liquid rapidly producing an identical decomposition, and separating the double salt into soluble sulpho-cyanide of ammonium, and white in soluble sulpho-cyanide of silver.

This decomposition of the double sulpho-cyanide by water is, as we shall soon see, upon studying the practical conditions of fixing, a very serious inconvenience inasmuch as it compels the operator to submit each proof to two successive fixings, separated by a washing in water.

This property also brings notable variations in the limit of saturation of the solutions of sulpho-cyanide of ammonium of different degrees of strength, and it is very evident *à priori*, that an equal quantity of sulpho-cyanide of ammonium will dissolve much less of the salts of silver, of chloride for example, as the quantity of water in which it is itself dissolved is increased. This we have proved by direct experiment. For,

100 parts of sulpho-cyanide of ammonium dissolved in 100 parts of water, dissolve 26 parts of chloride of silver.

100 parts of sulpho-cyanide of ammonium, dissolved in 200 parts of water, dissolved only 19½ parts.

100 parts of sulpho-cyanide of ammonium dissolved in 400 parts of water, dissolved only 14¾ parts.

So that there is an advantage and economy in dissolving a given quantity of sulpho-cyanide of ammonium in as little water as possible.

Preservation of the Bath.—An important consideration which demands all our attention is this:—Do the baths of sulpho-cyanide deteriorate like those of hyposulphite of soda when they are charged with salts of silver? Experience has shown that a solution of sulpho-cyanide undergoes a similar change, whether it contains silver or not. Besides the compounds formed in it are not, in any respect, of a nature to injure the permanence of a proof; a small quantity of a yellow powder (sulpho-cyanogen) is precipitated, and the bath exhales a faint odour of cyanuret compounds.

A simple filtering will remove the sulpho-cyanogen which renders the bath turbid, but the cyanide of ammonium will remain dissolved. Perhaps this compound, the action of which upon the proof is necessarily energetic, may exercise some influence, good or bad, upon the proof. Of this, experience will instruct us, but what theory at present teaches us is, that a bath of sulpho-cyanide does not acquire, by becoming old, any element destructive to the proof. The stability of the compounds under consideration is such, that the fixing baths may even, without danger, be acidulated with acetic, tartaric, citric, and other acids.

*Practical conditions of Fixing.**—The proof, before being submitted to the bath of sulpho-cyanide of ammonium, must be washed under the same conditions as a proof in-

* If the proof be fixed after it is toned, it will be well to carry this a little further than ordinary, for the sulpho-cyanide of ammonium appears to attack the proof a little more than the hyposulphite of soda.

tended for hyposulphite of soda. By thus removing all the nitrate of silver, we economize the fixing salt, but that is the limit of the effect of washing; for, it must be remarked, that in this case, the presence of nitrate in excess does not present the same danger as when hypo is employed; a drop of a solution of sulpho-cyanide may fall upon a nitrated proof with impunity, for it does not spot it; the fingers impregnated with this fixing salt produce no marks or stains; in a word, there is nothing to fear of such accidents that so commonly accompany the use of hyposulphite of soda.

The proof is afterwards immersed in the fixing bath; the best conditions, it appears to us, are those of a bath of the strength of 30 to 40 of sulpho-cyanide to 100 parts of water. With a bath made in these proportions we can fix with 1500 grains of sulpho-cyanide, 3 or 4 sheets 16×20, previously washed.

The fixing takes place a little more rapidly than with hypo, five to six minutes in the fixing bath will be sufficient. At the expiration of this time the proof is removed from the fixing bath and immersed in a dish of plain water, then will appear the only inconvenience this new method presents; the double sulpho-cyanide with which the paper is impregnated becomes decomposed, and small quantities of this substance remain interposed in the substance of the paper. To diminish that proportion as much as possible, we must take the precaution of draining the proof on removing it from the fixing bath. A second operation is then necessary to cause the last portions of silver the paper retains to disappear; it consists in passing the proof into a bath like that first employed. On removal from this bath the proof is again washed in plain water, and if the latter remains untroubled, it indicates that the proportion of salt of silver removed by the second bath is so small in proportion to the sulpho-cyanide of ammonium, that the double salt is no longer decomposed by the water.

If, however, this decomposition manifests itself again after the second fixing (although we have never encountered this inconvenience in practice), we must proceed to a third similar operation. The quantity of silver introduced by the proof into the second fixing bath is so small that it may pass for a new bath, when the first has become saturated, and consequently may take its place, and serve for the direct fixing of washed proofs. This is an important consideration in an economical point of view.

Finally, we remove the last traces of the fixing salt by simple washings; these washings are much shorter than with hyposulphite of soda, and it is easy to recognize their limit by adding a drop of the salt of the peroxide of iron to the washing water, which, if the alkaline sulpho-cyanide be present, will produce a blood-red colour.

The sulpho-cyanide of ammonium, and the alkaline sulpho-cyanides generally, which, as we have recognized, behave exactly like the salt which M. Meynier proposes to employ, present important advantages, the principal of which are: 1st. The certainty of never producing sulphurous compounds, which gradually destroy the proofs; 2nd. The absence of all fear respecting spots on the proofs; 3rd. The probable preservation of the fixing bath. To these advantages M. Meynier thinks we may add that of the perfect innocuity of the sulpho-cyanides; but we cannot speak on this point, for we are perplexed between the assertion put forth by M. Meynier and the statement contained in all treatises on chemistry to the effect that hydrosulpho-cyanic acid is poisonous.

Beside these advantages we perceive only two inconveniences: 1st. The necessity of operating with two successive fixings, a necessity which, unfortunately, will cause many photographers to ignore the advantages of the new fixing salt; 2nd. The high price of the sulpho-cyanide, which, at present, render its employment too expensive; but we must not omit to remark that this inconvenience will soon disappear, for the processes employed, first by M. Meynier for extracting the sulpho-cyanides from the condensing waters of gas works, and, secondly, that proposed by M. Gelis, for manufacturing the cyanides by means of sulphide of carbon,

will soon admit of photographers obtaining the sulpho-cyanides at a price nearly as low as that of hyposulphite of soda.—*Bulletin de la Société Française de Photographie.*

THE NEW ART OF AUTO-TYPOGRAPHY.*

BY GEORGE WALLIS.

THERE are several methods by which the drawings can be made, but I shall confine my attention to describing and illustrating those which have been most successful up to this time. The material may be paper of suitable texture, such as fine India post, or sheet gelatine, or the drawing may be made on the surface of the plate to be engraved, or on the plate-glass bed of the machine.

When a drawing is made on paper there is a choice of two methods. One is to make the drawing with a glutinous ink, which, when apparently dry, will, by floating it upon the surface of water, or damping equally at the back, become so far wet again as to take up fine particles of emery or other hard granular substances reduced to a powder. The effects produced are bold and effective, but rather coarse, as the examples shown indicate. The other method is to make the drawing with the same material as that used in executing a drawing on sheet gelatine, on the plate, or the plate-glass bed of the machine.

These drawings on paper when engraved produce a tint all over the subject, the result of the texture of the paper itself. This tint may be very usefully employed in producing gradations of tone, when treated with a mezzotinto scraper and burnisher.

The material for executing the drawings on sheet gelatine, &c., presented the greatest difficulty and cost some hundreds of experiments. It is composed of peroxide of tin, peroxide of manganese, Indian or Venetian red, Paris white, rice starch, gum arabic, and bichromate of ammonia, the latter being used for the purpose of converting the gum and starch into an insoluble resin, so as to permit of the repetition of the touches of the drawing, without disturbing the work previously executed. The relative proportions of the ingredients of this drawing material, which requires special care and experience in its preparation, are given in the specification of the patent,† by which the invention has been secured, and therefore need not be quoted here, as, of course, modifications are made for the purpose of producing special effects, of which the practice of the art can alone show the use.

This drawing material is classified for use as No. 1, with which the outline and basis of the drawing is executed; No. 2, which is darker in colour, is used to re-touch parts requiring greater force than that produced by No. 1; No. 3 is sometimes used for producing very strong granular effects in the shadows, but generally I think it best to avoid its use.

One great peculiarity of this process is the production in the metal plate of the effects produced by broad washes and touches executed with a brush, somewhat of the character of aquatint. These broad effects are produced in the drawing by the washes being thrown in after the simple outline of the subject is obtained with material No. 1, by means of a special material, which, for convenience, is called Tint A, to indicate its use. A more granular modification of this mixture, Tint B, is used to obtain greater force in such parts of the washes as the artist may deem desirable.

The drawing instruments used are pens, metallic or otherwise, of suitable quality as regards fineness or breadth of point, and the ordinary sable brushes used in water-colour drawing.

When a drawing has to be executed, say on sheet gelatine, the material is selected of as even thickness as possible, and with the surface upon which the drawing is to be made free from spots, bubbles, or other blemishes, as these will come in contact with the plate during the operation of engraving, and all defects will be re-produced as well as the artist's work. The piece of sheet gelatine is mounted in a card board mount, the "sight" being cut to the size of the plate in which the drawing is to be engraved. (A specimen properly mounted was shown.) Over the back is placed a piece of tissue paper, fastened only on one side, so that it can be turned back, while the subject is traced upon the gelatine with the drawing material No. 1, from a study prepared for the purpose, and as the gelatine is as trans-

* Continued from p. 200.

† Patent No. 1,299, 1860.

parent as glass, of course this tracing can be done with the greatest nicety. The outline being secured, the piece of tissue paper is then returned to its position, and the drawing has much the appearance, when looked through, of being executed on ground glass.

To facilitate easy execution I have invented a drawing desk with a glass top fixed in a frame. This can be placed at any convenient angle, and by this desk being placed so that the artist can sit opposite to the light, with a piece of white paper on the bottom of the desk under the glass, the light is thrown through the partly executed drawing, and every facility is thus given for finishing it with all the force and effect of which the process is susceptible. (A specimen of the desk was shown in use with a lamp.)

The drawing materials, being in the condition of powder, are mixed for use by taking a small quantity of the gradation required and adding to it sufficient water to make it flow easily and continuously from the pen. If used too thin, however, the lines produced in the engraving are not forcible, and the principle of the invention must then be borne in mind, viz., that the lines will engrave in proportion to their substance, just as the natural object engraves according to the thickness and density of its substance. In this fact lies the whole condition of a successful drawing, and perhaps I could not give a better illustration than by reminding the artist that, as in oil painting, the impasto, or loaded portion of the drawing is in the lights, the reverse is the case in autotypography, for the deeper the shadow required the higher the relief of the drawing material should be off the surface of the drawing, as the greater will be the intaglio thus produced in the plate. Of course it would be hopeless to attempt to give precise rules for producing special effects. We are dealing with an art, and to know it it must be practised; and I believe that it has this merit, that the impress of the mind and manual dexterity of the artist will add to the great charm of the results produced, whilst the limit, under certain conditions, is simply that of the ingenuity and skill of the executant.

The drawing being ready for engraving, which it is as soon as dry—that is a few minutes after it is finished, although as a rule it is better to let it stand for a few hours—it is taken to the machiuo.

The machine now before you is a working model of improvements suggested by the experience gained in the construction of our four times the size, and by which the larger specimens have been produced. This consists essentially of a pair of rolls mounted on horizontal axes. The bearings of the lower roll are fixed, whilst the brasses of the upper roll in which it turns are capable of a vertical sliding motion in the side standards. By means of side screws and hand wheels the upper roll is raised or depressed. In this small machine the wheels are engraved with gradual degrees for the indices of pressure, which can be regulated to the 1520th of an inch by the usual relation between the rotation of the index wheels and the thread of the screws. The edges of these wheels are notched or toothed in correspondence with the graduated degrees, and a fixed index with a spring engages as the wheels are moved, thus indicating both the pressure and parallelism of the upper roll with the lower. Between the two rolls a horizontal table or bed, which is supported by steel spring bars, is made to slide. The table may be made entirely of metal, but in this instance it is made of steel with a well, into which a piece of plate glass is fitted and securely embedded upon a sheet of gutta-percha. The plate-glass possesses great advantages over metal, both as regards surface and non-oxidization, whilst the facility with which it can be removed, when required, from the well or metal frame for convenience in drawing upon is of great importance.

The rolls are made to revolve by means of a worm-wheel attached to the axis of the lower roll, but working outside the framework. Motion is communicated by a worm which drives the wheel, the power being applied to a hand-wheel or winch attached to the lower end of the worm axis or shaft, which works within a bearing and hanging bracket attached to the frame of the machine. The rotation of this shaft and worm communicates a slow and steady motion to the lower roll, and as this is geared on the opposite side to the upper roll by means of toothed wheels, the rolls rotate simultaneously.

The method by which a plate is engraved has now to be described. The thickness of the plate being gauged by one of Whitworth's decimal gauges, the indices are turned to the particular degree indicated by that thickness, with an allowance

of the 50th of an inch, and the thickness of the gelatine, which may be calculated at another 50th, as engraving pressure. It should be borne in mind, however, that the gelatine is elastic and yields probably full one-half its thickness, so that the *plus* pressure beyond the gauge of the plate may be taken at about the 30th of an inch.

The metal plates used are a good quality of Britannia metal, and, so far as experience goes, these print a fair number; but by taking advantage of Joubert's process for steeling the surface, or producing an analogous effect by means of nickel, the plates yield a considerable number of impressions; and, as the drawing is comparatively uninjured by the process, several plates of the same subject can be produced from one drawing by a careful examination of it, and a little retouching in such parts as may appear worn or deteriorated by the pressure in the operation of engraving. In some instances, as many as six plates have been produced from one drawing, and it is still available; and, unless injured by damp or some accidental cause, will be available for years to come.

It will be evident, from the nature of the process, that it possesses several advantages over any other in use for the reproduction of the artist's work direct from his own hand. Thus:—

1. There is no reversal of the subject required, as it is drawn exactly as it is to appear when printed.
 2. A plate can be engraved and proved to show the state of the drawing. The latter can be worked in again, and again proved, and this can be repeated until the desired effect within the limits of the process is produced.
 3. The transparency of the sheet gelatine gives great facility for copying drawings, by tracing all the leading features; and, of course, this applies to photographs, which may be largely used as guides, and art thus made to supplement science, since the artist has the power of selection in reproduction of the forms of the photographs by autotypography.
 4. The rapidity with which designs, drawings, &c., may be reproduced, when they are once executed by the autotypographic process, which, as already stated, becomes with a slight degree of practice, as easy as ordinary sepia or India ink drawing.
 5. The fact that the artist can retain the plate in his possession, and have such a quantity printed at a time as may best suit his convenience, as in the case of an etched plate.
- In all the illustrations given it must be distinctly understood that no after process, or any retouching whatever, has been used. All the examples are the result of the autotypographic process, pure and simple. It must be quite clear, however, that some of the effects could be rendered much more positive and telling by judicious touching up with the graver and etching needle. As, however, it would have been difficult to have defined where the process which is the subject of this paper ended, and that of touching up began, it was thought desirable that none should be shown which had been so treated. It must be clear, however, that for practical purposes those well known means of increasing the force of an engraved plate would be largely available when required.

There are only two points now to consider, and this paper may be brought to its conclusion.

The first is—Can the process be regarded as complete? To this I answer, as the inventor, that so far as the effects already attempted are conceived, it may be, but I feel satisfied that in the hands of an ingenious artist, fertile in resources as regards the production of delicate and even powerful effects, it is susceptible of very great development. This however depends upon one point, to which I am particularly desirous to have attention paid on this occasion in any remarks which may follow this paper, and that is, whether in the present advanced condition of the art of illustrative printing in its varied forms, this process is worthy of special attention and further development.

The second point is the purposes to which, if this question is settled in the affirmative, the process can be artistically and economically applied. Under the latter head we may range the reproduction of artists' sketches at a comparatively cheap rate, the plate being held for use at any period subsequent to the reproduction; also plates for book illustrations and the production of portraits in a metal plate by the aid of a photograph, the autotypographic drawing being worked upon from life, if necessary. The portraits so produced are, of course, as permanent as those printed from ordinary engraved plates. In the

industrial arts, the production of transfer plates, especially for the "bat" process for the decoration of porcelain, appears to afford a considerable field of operation, as the drawing produced by the original artist is reproduced on the ware; and outlines drawn by a first-class artist may be transferred to the surface of an article in porcelain, to be filled in with colour by the artist workman, whose technical knowledge is thus used to the greatest advantage. It must be evident, too, that metallic surfaces being planes, may be decorated in a novel and effective manner by painting upon the metal plate the design intended to be engraved, and then submitting it to the action of the machine. Results may be thus obtained which no engraving with a point could possibly achieve, and these effects may be further enhanced by working upon with the graver.

Of course it is impossible to calculate what ingenious persons may make of any invention at the outset. Experience has shown that the most unpromising in the beginning have come out triumphantly in the end; and it is equally true that many processes of apparently great value and probable usefulness when first developed, have sunk into oblivion before the test of practical and every-day application. Whether the process I have brought before the Society of Arts in this paper belongs to the one category or the other, it would be presumptuous to pronounce too distinctly in its present stage. I may be allowed, however, to state, in concluding this description of its purpose and leading features, that the main object I have had in view in following up a series of experiments extending over more than four years, at no little cost of time and money, has been the improvement of the arts of my country, both pictorial and industrial, by bringing the artist himself nearer to the reproduction of his own work, and affording a means by which the impress of the original mind and hand shall be conveyed in a permanent form, for easy reproduction in considerable numbers, at a comparatively cheap rate.

As a matter of interest to the members of the Society of Arts, I think it a duty, as it certainly is a pleasure, however largely mixed with sorrow, for me to state, that the late lamented President of the Society, His Royal Highness the Prince Consort, expressed a very distinct and favourable opinion of the process in its application to various branches of art, when specimens were submitted to him, and a desire to know more of the practical working than could be given by mere description; but his premature removal from his earthly sphere of usefulness prevented the fulfilment of arrangements proposed for meeting his wishes. We all know the intelligent interest with which he invariably investigated all matters which seemed worthy of attention, or likely to prove useful to the arts and sciences of his adopted country, and his readiness to encourage, by kindly words and judicious advice, efforts which he believed to be in the right direction. To myself, although greatly encouraged by the favourable opinion expressed, it would have been a source of infinite satisfaction to have submitted the whole process to the judgment of one so able to appreciate its value on the one hand, or detect its defects on the other.

PHOTOGRAPHIC PIRACY OF ENGRAVINGS.

(*Sittings at Nisi Prius, at Guildhall, before Mr. Justice Williams and Common Juries, April 27.*)

GAMBART V. MAYNE.

Mr. Collier, Q.C., and Mr. Brandt were for the plaintiff, and the Hon. G. Denman, Q.C., was for the defendant.

This was one of a series of actions brought by Mr. Gambart, of Pall Mall, the well-known publisher of works of art, with the view of endeavouring to protect his copyright in the engravings which from time to time he brings out. The plaintiff has for some time past confined his dealings to paintings of the highest character, and has given very large sums for works of merit. He gave £5,500 for "The Saviour in the Temple," by Mr. Holman Hunt, which is the largest sum ever paid for a modern picture. Having become the owner of a painting, he has it engraved in first-rate style and at great expense, and for the engravings, which are first-class in their character, he obtains from two to ten guineas each. Since photography was arrived at such a state of perfection, facsimiles of his plates have been taken by that process, and from the negatives so obtained copies are printed, which in some cases are little, if at all, inferior to the plaintiff's ten-guinea engravings, but which can be sold with profit for from 1s. to 5s. a-piece. A league has been formed by publishers of engravings for the purpose of putting

down this practice, but Mr. Gambart prefers suing on his own account, and single-handed.

In the present case, he complained of the infringement of his copyright in a very beautiful engraving, copies of which are to be seen in the windows of many dealers in engravings and prints, both in London and in the country. It represents our Saviour holding a lantern, and knocking at a rustic door, and is known by the name of "The Light of the World." The original painting is by Mr. Holman Hunt, and Mr. Gambart had expended upon the engraving, purchase of the copyright, &c., nearly £2,000. The defendant is a stationer and proprietor of a circulating library at Exeter, and photographic copies of Mr. Gambart's engravings having been seen in his window, in 1861, he was written to on the subject by that gentleman's agent, but no satisfactory answer was obtained from him. In October, 1862, Mr. Gambart having employed Mr. Bowen May to conduct his legal business, Mr. Wakeford May, who is clerk to his father, happening to be on a visit in the neighbourhood of Exeter, bought a copy of Mr. Gambart's "Light of the World" from Mr. Mayne, the defendant. Letters were written by Mr. May offering to forego all proceedings if Mr. Mayne would give up any copies remaining in his shop, and the names of the persons from whom he had obtained them, pay a small penalty, and promise to offend no more. No settlement could be effected and he therefore brought this action.

The plaintiff having proved his copyright in "The Light of the World," Mr. Thomas Ward, of Exeter, was called to show that he had bought two photographs of Mr. Gambart's engraving at Mr. Mayne's shop, and that he saw there about 10 other copies of the same print, but inasmuch as his purchases had not been within six months of the date of the commencement of the action, the plaintiff was limited in his proof to the photograph bought in October by Mr. Wakeford May, which was a very small one, much smaller than one bought by Ward. Mr. Gambart, however, said that the sale of even these diminutive copies was very detrimental to the sale of his engravings. He had exhibited the original painting in Exeter, and had, up to the time of the introduction of the photographic copies, realized there £800 by sales of his large engraving, but not a penny since. He urged it as his opinion that the public were satisfied with a photograph as a kind of reminiscence of the subject, especially when it was of a religious nature. In this view he was borne out by Mr. Graves, the eminent publisher, who said that a purchaser of the photograph had a small but exact reproduction of the original, and that in fact a photograph might be as large as the engraving of Mr. Gambart. Several points of law having been raised on behalf of the defendant, and reserved by the learned judge,

Mr. Denman addressed the jury and called his witnesses.

The defendant proved that he had sold no copies of "The Light of the World" since April last; that Mr. Wakeford May came into his shop in October and asked for a photograph of that engraving, and that he (Mr. Mayne) had told him that he had sold none lately, for that there had been a fuss about them. His daughter came in, and he said, "We don't sell 'Lights of the World,' do we?" and she answered, "No, certainly not." Mr. May then appeared very anxious to have one, and Miss Mayne said she thought she had a small copy, which had been given her by a Mr. Brewer. Mr. May said he should like to see it, upon which she went into a back room and brought the one which had been produced at the trial. Mr. May said it was a very poor one, and he would rather have a larger one. He then asked what he was to pay, and the defendant said "Nothing." Mr. May, however, insisted on paying, and eventually he did pay 6d., which Miss Mayne claimed. On this a Mr. Farrant, who was in the shop, observed, "Bravo young lady, I like to see you stick up for your rights." Mr. May bought three other photographs, and paid 3s. for them.

The defendant's evidence having been corroborated by Miss Mayne, Mr. Brewer, and Mr. Farrant.

Mr. Justice Williams asked Mr. Collier if he could carry the case any farther?

While the learned council was arguing the point, the foreman of the jury rose and said that there ought to be a verdict for the defendant.

Mr. Collier begged to say on behalf of Mr. Gambart that the defence had come upon him entirely by surprise. The defendant had not in his letters hinted at any such state of facts.

Mr. Justice Williams said Mr. Gambart was actuated by the most praiseworthy motives as he had a very valuable property to protect.—Verdict for the defendant.

Proceedings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

The usual monthly meeting of this society was held on the evening of Wednesday, April 22nd, at Myddelton Hall. Mr. G. Shadbolt in the chair.

The minutes of the previous meeting having been read and confirmed, the following gentlemen were elected members of the society:—Messrs. C. Wright, and C. Henneman.

Mr. COLLIS exhibited some views in Portugal, taken by Mr. Munro, an amateur, with Ross's panoramic and triple lenses. Also some fine card portraits, by Southwell and others, with his card lenses. Also a very fine photograph, 26 inches by 20 inches, of a *bas relief* in Spain, by the late Mr. Clifford.

Mr. G. WHARTON SIMPSON exhibited some very beautiful crystals of the double sulphate of iron and ammonium, by Messrs. Hopkin and Williams.

A conversation on the use of the double salt as a developing agent followed.

The CHAIRMAN showed some good stereographs from negatives by a new rapid dry process; and also some card portraits of celebrated men in America.

Mr. MORLEY showed some good negatives on Fothergill plates, treated after drying with a mixed solution of tannin and gallie acid. Some conversation on the subject followed, in which Mr. Morley, in reply to a question, said he thought that the gallie acid gave more intensity than tannin alone.

Mr. MAINWARING showed a stereograph of a wedding party, the negative of which was taken in four seconds. It was developed and intensified with iron, a solution containing 5 grains of iron and 5 grains of citric acid being used for intensifying.

Mr. G. WHARTON SIMPSON then read a paper entitled "Practical Notes on the New Fixing Agents," (see p. 206). The thanks of the meeting being awarded by acclamation, some conversation on the subject followed.

Mr. SIMPSON showed a number of prints fixed with the sulpho-cyanides of various tones, from purple-brown to black, in all of which the whites were perfectly pure. He also showed a sample of sulpho-cyanide of ammonium, and some sulpho-cyanide of silver in a test tube, which had been exposed some days to diffused light without change.

The CHAIRMAN said the paper suggested several important points for discussion. In the first place the fact that the new fixing agent did not present many advantages for removing the unaltered iodide from negatives was not of serious importance, as hyposulphite of soda performed that office so well already. Its use for fixing albumenized prints was of far greater importance; and here, for the present at least, they were met with somewhat contradictory evidence. If he understood Mr. Simpson rightly he found that even with this fixing agent silver was still present in the whites.

Mr. SIMPSON pointed out in some of the sulpho-cyanide-fixed prints exhibited the characteristic brown stain in the whites, produced by contact with sulphide of ammonium.

The CHAIRMAN resumed that Messrs. Davanne and Girard had said this salt was a solvent for albuminate of silver, and had also stated that the presence of silver in the whites of even hypo-fixed prints was due to some slight exposure to light, during the printing processes, and that if the same care were taken to keep the sensitive paper from all contact with white light which was taken with the collodion plate, we might avoid the traces of silver in the whites.

Mr. SIMPSON said that this was a very ingenious theory, but unfortunately for it Mr. Spiller's experiments quite disproved it. He excited albumenized paper, and then washed and fixed it with new hypo, without even taking it out of the dark room, or allowing it to have the slightest exposure to light. Yet this, when fixed and thoroughly washed, showed the presence of silver when tested with sulphide of ammonium, and yielded silver on analysis. In reference to the remark of Messrs. Davanne and Girard to the effect that the sulpho-cyanide of ammonium was a perfect solvent of the albuminate of silver, they had also remarked that after treating the combination of albumen and silver with this salt they found only very *small traces* of silver remaining. But if it were a perfect solvent no trace whatever should have remained.

The CHAIRMAN next referred to the possibility of testing for the final traces of sulpho cyanide in the fixed and washed prints, and said he did not think the iron test would be a sufficient

guide. Nitrate of silver was a very delicate test for hypo, but it was possible for the print to show no trace of hypo when tested with silver, and yet be imperfectly washed.

Mr. SIMPSON agreed with the Chairman that much stress could not be placed upon this test. But he thought that probably less danger was to be apprehended from traces of the sulpho-cyanide of silver remaining in the print than from traces of the hyposulphite of silver or soda. Either of the latter were very unstable, and free sulphur was liberated by their decomposition. This, it appeared, was not the case with sulpho-cyanide of ammonium or sulpho-cyanide of silver, for although sulphur could of course be liberated, it was much less liable to be so than from the other salts. It was possible that some danger was to be apprehended from the peculiar fact that the double sulpho-cyanide of ammonium and silver formed in the course of fixing, was decomposed by water into soluble sulpho-cyanide of ammonium easily washed away, and insoluble sulpho-cyanide of silver, traces of which would probably remain in the print. What damages must be apprehended from this, time would show.

The CHAIRMAN referred to the irritant influence of this and other fixing salts, such as cyanide of potassium on the skin, and remarked that he understood from a medical friend that it was rather from the potash than the cyanogen that the irritation arose, and that probably carbonate of potash would have a similar effect.

Mr. SIMPSON said that he had not referred to the irritation in the finger as any proof of the poisonous character of the salt. Authorities on that subject appeared to differ, and he had not made any experiments in that direction.

Mr. SIMPSON then placed a portion of the sulpho-cyanide of silver which had been exposed to light, in a glass, and pouring a little solution of sulpho-cyanide of ammonium upon it, showed how readily it was dissolved. He pointed out the advantage this offered in the case of imperfectly fixed prints, which, instead of being destroyed, could be properly fixed subsequently; and also showing that from this fact there was no danger of staining the print by touching it with the fixing salt as was the case with hypo.

Mr. MAINWARING asked if cyanide had been tried for fixing prints?

The CHAIRMAN said he remembered the same question being asked at the Photographic Society, when one gentleman replied: "He had tried it;" and, on being asked the result, laconically replied, "Out."

Mr. SIMPSON said the misfortune with cyanide was, that it did not discriminate between the unaltered chloride of silver and the reduced chloride which formed the half-tones, and these were generally destroyed by the cyanide.

The CHAIRMAN corroborated this view, and said that cyanide was not only a solvent for chloride of silver, but for metallic silver itself, when in a sufficiently fine state of sub-division, as in the half-tones of prints.

After some further conversation the proceedings terminated.

Miscellaneous.

PHOTOGRAPHS OF SANDRINGHAM, &c.—The London Stereoscopic Company have, during the last fortnight, had a staff of artists engaged at Sandringham in taking portraits of the Prince and Princess of Wales, and of the house and grounds. They have, we understand, been very successful.

TO EXTRACT THE SILVER OUT OF OLD HYPO BATHS, BY MEANS OF METALLIC ZINC.—If a strip or stick of zinc is put into an old hyposulphite bath the silver will precipitate in the form of a black powder. The reaction is complete when the liquid begins to smell strongly of rotten eggs (hyposulphurous acid). The liquid is then thrown away, and the deposit is washed repeatedly, to get rid of the hypo, and is usually thrown on to a paper filter and allowed to dry. This precipitate is not metallic silver, but a mixture of this metal with sulphuret of silver. It can, therefore, be transformed into nitrate by dissolving it in nitric acid. To transform this deposit into metallic silver, it is mixed with its weight of dried nitrate of potash in a porcelain mortar, and thrown by small quantities into a bright, red hot crucible. When the whole mass is fused, it is kept on a brisk fire for at least fifteen minutes. The silver will then be reduced, and the crucible allowed to cool. On breaking it, the metal is found in the bottom.—*American Almanac of Photography.*

Talk in the Studio.

COAGULATING ALBUMEN ON ALBUMENIZED PAPER.—Mr. Wood says, in reference to the alleged difficulty which some have felt in effecting coagulation by steaming, that in his hands it is so simple that he would undertake, unassisted, to complete a ream in three hours, and warrant every inch perfectly insoluble.

MEDALS OF THE PHOTOGRAPHIC SOCIETY OF SCOTLAND.—Amongst the medals awarded by the Scottish Society for meritorious works at its recent private exhibition, we find that Mr. Meagher has secured one for excellence of workmanship and improvements in cameras. Also, that for printing in carbon, the committee would recommend that the medal be given to Mr. Pouncy, of Dorchester, for his view of Melrose Abbey, in which it appears to the committee he has overcome the difficulty of representing in carbon every variety of shade and tint exhibited in the original negative.

THE CAMERA FOR THE LANCASHIRE FUND.—We understand from Dr. Diamond, that the subscription list, making a hundred chances, at five shillings, for Mr. Meagher's handsome camera, given to the Lancashire Fund, is not yet quite filled. As the drawing will take place shortly, the Secretary is anxious to have the list filled up, and also to receive the subscriptions of those who have already entered their names. We commend the matter to the attention of our readers.

To Correspondents.

G. R. G.—The defect is that so commonly known as mealiness; it proceeds from a variety of causes, the majority of which originate primarily in some peculiarity of the paper or albumenizing. It may frequently arise in comparatively good paper from unsuitable treatment, and in some samples no treatment that we know of will entirely avoid it. A strong neutral or slightly alkaline silver bath, a good negative, well washing in distilled water, and slow toning with a gold bath at least a few days old, are the best modes of avoiding the evil. Some printers have found great advantage in bad cases from the use of a bath of acetate of soda previous to toning. We have never found it, when we have toned slowly, using a dilute acetate and gold bath, which has been made a week or more. In your case, from the results, we imagine the toning has been rapid. Where it shows before toning, it results either from the paper, or from an acid nitrate bath.

N. O. B.—We have never met with, or heard of, anything like the stained and leprous effect of the sensitive paper enclosed in your letter. If it simply result from floating on the nitrate bath without contact with any other substance, we cannot conceive the cause. The paper must have come into contact with some other chemical beforehand. The contact of salted albumen only, with nitrate of silver, could not produce such a result. It might possibly arise from some serious impurity in the paper.

PHOTOS.—The addition of three grains of carbonate of soda to one grain of chloride of gold, will frequently be sufficient to cause precipitation in 24 hours. We do not like the use of carbonate of soda on account of its uncertainty. Carbonate of lime being an insoluble alkali, answers the purpose of neutralizing much better. See a short article on the subject in the present number.

P. T.—Your communication must have miscarried, as we always answer or acknowledge in some way the receipt of letters, and we are always glad to receive suggestions which may be of service to our readers. Exposing an excited wet plate to the fumes of ammonia would, unless the bath were very acid, produce fog. It is a dangerous practice to keep chemicals of any kind unlabelled, especially composite acids. There are various methods of distinguishing between nitric, sulphuric, and hydrochloric acids. The presence of colour is not a test; when pure they are all colourless, but all assume colour from the presence of impurities; the yellow colour is most likely, however, to belong to the hydrochloric acid. Perhaps the simplest method for you to ascertain which acids the three unlabelled bottles contain will be to observe the following points: the nitric and hydrochloric acids both emit suffocating fumes, when the bottle is opened the sulphuric acid does not. To distinguish then between the two first, add a drop or two of each to a solution of nitrate of silver, with the nitric acid no visible change takes place; with the hydrochloric acid a white curdy precipitate of chloride of silver is thrown down. As a further test for the sulphuric acid, add a little to a solution of nitrate of baryta; a white insoluble precipitate of sulphate of baryta is the result.

A. FAIRBANKS.—You cannot secure a copyright in the portrait of one of your sitters without an agreement with him to that effect.

J. J. W., Eton.—Your cards have very good qualities. There is, however, a little too much even diffusion of light all round the figure. A little more direct light from one side, and a little more shadow on the other, will give you more force without losing definition. We are glad you have found our teachings so valuable.

H. P. C.—You will find various descriptions of developing boxes for field use in our back volumes. We may especially mention page 275, Vol. v. (No. 144), and page 381, Vol. v. (No. 153). A good portrait lens, when used with full aperture, does not possess much depth of focus, especially when used for objects very close at hand. To get depth of focus you must use a small stop, and in such a subject as that you name, you can afford to do so, without reference to the time of exposure. A still-life object, such as a group of porcelain, should be taken with the lens sufficiently stopped down to give the proper modelling and definition in every part. The simple lens

of the same maker is the best for such work, giving great depth of definition; but if you wish to work with your portrait lens, you will have no difficulty in obtaining depth of focus if you use a smaller stop.

M. A.—Unless the sample of chloride of gold be nearly neutral, the trace of alkalinity in acetate of soda will be insufficient to neutralize the acid. The free hydrochloric acid will decompose the acetate, and become neutralized by the soda, leaving free acetic acid. See our short article on the subject in the present number. The tone and general qualities of the print you enclose are very satisfactory.

A. B. C.—Thank you for the slip. As you would perceive in our last, we had already received and made use of it. Your bath is super-saturated with iodide or iodonitrate of silver. Dilute it with half its bulk of distilled water, which will at once make it milky-looking, place in the sun for a few hours, until the precipitate has fallen and the solution is clear; now filter, and then add sufficient nitrate of silver to make up the proper strength. The print received is from an under-exposed negative. If it had received longer exposure it would be brighter and more harmonious.

P. M.—So far as we know, No. 2, but we do not speak from personal experience. Either of the English, we believe, are superior to the French lenses.

W. H. H.—There is some difference in the solubility of different samples of tannin; but we have not met with any which did not with proper agitation dissolve in the ratio of 15 grains to an ounce of water. There is often a slight deposit of resinous matter which must be removed by filtration, after which it may appear opaline, but not turbid. In preparing gum and tannin it may be better to dissolve and filter each separately, and then mix. We cannot tell you where to obtain malt except from a maltster or brewer. Prepare it by infusion, using three or four ounces of malt to a pint of boiling water.

CUMBERLAND.—The chief fault in the card sent arises from the fact that both the sitters, or the plate, have moved. In the next place the negative is considerably over-developed, and the print not sufficiently deeply printed. Even when operating in the open air you should contrive some means to obtain shadows. The light is equally diffused all around your sitters, which destroys force and modelling. Read a recent article headed "Amateur Portraiture."

A LADY AMATEUR.—The red streaks on the prints in your letter are apparently due to imperfect albumenizing of the paper. The albumen appears to have run in streaks, and those parts where it is most present refuse to tone.

A CONSTANT SUBSCRIBER.—The plate commonly used for the stereoscopic negative is 6½ inches long, and it is customary, in the absence of any instructions to the contrary, on the part of camera makers to place the lenses on a bi-lens camera at a distance of 3½ inches from centre to centre. This is a very good distance, as, when the print is produced, each half can be trimmed all round, which, if the images were much nearer together, could not be done. The distance should never be less than 2½ inches apart, and may be a little more without disadvantage. According to strict rule, as stated by some authorities it should not exceed the distance between the eyes, whilst others would regulate the distance according to the character of the view, making it, for very distant objects, several feet apart. We think the latter in error, but it is not necessary to adhere absolutely to the former.

DUTIES OF A PHOTOGRAPHER'S APPRENTICE.—A correspondent familiar with the law writes as follows:—"As you have said, 'W. R.' cannot legally enforce the apprentice to learn a different profession to the one which is mentioned in the indenture. It is very evident from the wording of the indenture—and particularly from the fact that no mention is made in it of painting photographs—that 'W. R.' is bound to teach his apprentice the art of a photographer and not that of painting photographs; and the apprentice would be perfectly justifiable in refusing to do anything but what is stipulated in the said indenture. Of course this opinion is grounded upon the supposition that the wording of the deed is in no respect different from what 'A Constant Reader' uses in his recital of it. If the indenture states that 'the apprentice shall be taught the art of photography and its branches' the master is at perfect liberty to teach and enforce the teaching of his apprentice in anything which relates to photography."

W. STONEHOUSE, Whitby, sends us some very charming card portraits, taken with Dallmeyer's No. 2 B lens. They are beautifully defined, round, soft, and delicate. The lighting is very successful, and the composition generally good. No. 6, a young lady in profile, lighted chiefly from behind, is very fine. The fish-woman is a good photograph and characteristic picture. No. 4 is a good photograph, but as a composition it is cut up into two parts a little too definitely by the curtain, &c. No. 2 is a capital composition. As a whole we like the pictures much.

A. WOOD.—We are obliged for the prepared paper and further details. We hope to try it in a day, and will report with what success. The specimen enclosed is very good. Several correspondents in our next.

EXPERIMENT WITH IODIDES AND BROMIDES IN COLLODION.

In conducting experiments all the conditions at every stage of which are well known and familiar, the experimentalist is apt to be guided in his estimate of the result by foregone conclusions. It is well, therefore, sometimes to begin *de novo* without a knowledge of some element in the calculation, so as to reach conclusions without any settled conviction in the mind of what must happen.

A few days ago a manufacturer of collodion sent us three sample bottles to report upon. They were labelled No. 1, No. 2, and No. 3, but no clue of any kind to their special character or preparation was given, beyond the fact that they were especially intended for card portraiture, and that the manufacturer was desirous of having independent testing or verification of his own results before making largely for the public. He felt, therefore, that a report, unbiassed by any possible prepossession, would be best obtained by withholding any details as to haloid salts, and their proportions, present in each.

We proceeded to take a card negative with each, exciting in a nitrate bath in excellent condition, giving us fine results with various samples of collodion we had in use. We used a Dallmeyer's No. 1 B lens, with a stop of about half an inch aperture, giving in each instance, five seconds' exposure in the open air. We developed with a strong solution of saccharo-sulphate of iron. The result of the first trial of each sample, hastily jotted down at the time, but verified by repeated experiments since, was as follows:—No. 1, lights developed quickly, but half-tones appeared tardily; finished image thin, grey, and under-exposed, with fogged shadows, profusion of spots, and comets. No. 2 developed in every way satisfactorily, the image was brilliant, the high lights well picked out, the half-tone delicate, and giving great modelling, shadows clean, the negative sufficiently vigorous, with the first application of the iron solution, to print well without further intensification. No. 3: the result was in many respects similar to those of No. 2; a very soft image, but sufficiently dense to print without further treatment; a little more deposit on the shadows, and the general effect of being a little more done, the sparkling high lights giving force and brilliancy in No. 2, being wanting in No. 3.

On rendering this report to the maker of the collodion, we learnt that in each instance the normal collodion was the same, the sole difference being in the salts used, which were as follows: No. 1 contained $4\frac{1}{2}$ grains of iodide of cadmium in each ounce. No. 2 contained the same quantity of the same iodide, with the addition of one grain of bromide of cadmium. No. 3 contained the same quantity of the same iodide, but in addition $4\frac{1}{2}$ grains of bromide of cadmium to each ounce. The results in his hands had been similar to those in ours, with one interesting difference, illustrating another point: No. 1 in his hands was less sensitive and less satisfactory than the others, but instead of yielding a

thin grey image, it gave a negative with great density and contrast, but without half-tone or harmony. The difference in the experience of each was easily explained. We had used a bath somewhat freely acidified with nitric acid, whilst he had used a neutral bath. The presence of nitric acid in the bath was, in the days of simply iodized collodion, a familiar cause of thin grey negatives, and proved so in this instance. Some subsequent experiments with a neutral bath gave us similar results as to sensitiveness; but whilst with No. 1, the simply iodized sample, we then got rid of the thin grey image, it was still spotty and slow, and yielded less brilliant prints than a negative taken with No. 2 under similar circumstances.

The results thus secured, and the conclusions attained, without the possibility of foregone convictions influencing the decision, confirms in a very satisfactory manner all our established conclusions, the results of numerous carefully conducted experiments several years ago, and repeated at intervals since. For portraiture and general purposes a collodion made from cotton which will dissolve not less than six grains to the ounce of solvents, and containing from a grain to a grain and a half of a bromide, and from four to five grains of an iodide, either cadmium alone, or half cadmium and half an alkaline iodide, we regard as decidedly the most stable and best for iron development, yielding, with short exposure, harmonious and brilliant negatives. For many special purposes a larger proportion of bromine may be permitted, for the general purposes of the portraitist, however, it is unnecessary and sometimes injurious.

THE ENAMEL PHOTOGRAPHIC PAPERS.

As the enamel papers for card portraiture appear likely to excite some interest amongst photographers, it is important to obtain as much information as possible as to their original preparation, the treatment they require, and the qualities they possess. At present the information on the subject is very scanty, owing to the existence of "trade secrets;" we have, however, gleaned a few additional particulars.

There are, so far as we know at present, three distinct manufacturers of the enamel photographic paper all in Germany, namely, Liesegang, Schering, and another whose name we do not at this moment recall. Of the material employed in giving the preparatory enamel surface we only know that employed by Herr Liesegang, the other two houses preserving the matter a secret. Herr Liesegang, himself an able photographer and chemist, knowing the importance to the photographer of having some knowledge of the nature of materials with which he is working, does not withhold the information. The pigment employed in enamelling, he informs us, is oxide of zinc. Referring to the suggestion, in the letter of a correspondent, recently made in our columns, to the effect that his paper was really prepared by Mr. Schering he writes as follows.—

"The paper of which I sent you a specimen was prepared,

after my suggestion, in the manufactory of my father. The enamel is a preparation of zinc-white, and the albumenizing is done in the ordinary manner. The albumenizing not being different from that of ordinary paper (the solution being only a little more salted because the film is entirely on the surface) there is no reason why it should be treated in any other way."

The samples we have seen of the three makers vary in qualities. That of Liesegang has a less highly glazed surface than either of the others, but it is more free from tendency to crack, and, altogether, presents the fewest manipulatory difficulties. In fact, we have treated it as precisely ordinary albumenized paper, and found no difficulty whatever in obtaining excellent results.

The sample with the highest surface was that we received from Mr. Jocelyn, details regarding which we recently published. The quality was very fine, but it required great care in treatment to avoid cracks.

The paper, prepared by Schering, which he styles alabaster paper, not enamel, takes a position midway, both as to surface and as to facility in manipulation, between the last mentioned and that prepared by Liesegang. We have recently received communications on Schering's paper, both from Mr. Spencer and from Messrs. Johnson and Matthey. We glean from them that the first sample of this manufacture which arrived in this country was somewhat prematurely introduced, before its manufacture was sufficiently perfected, and that a judgment formed on such a sample will scarcely do it full justice. We have received a sample of a fresh arrival, to which we have not had time, however, to give a fair trial. One of the claims made for the alabaster paper is that it does not crack under fair treatment. We must warn our readers, however, that unless pinned at the four corners when lifted from the silver bath, it will curl and will crack. Indeed, the sample which reached us, rolled up, was already slightly cracked, and would have been better if it had been set out flat. The tendency to crack seems to increase with the proportion of the enamel pigment present, and hence the thinnest papers, with least of the enamel pigment, present the least difficulty. We have tried the sample in question, so far as to be able to say that in our hands it has not given the streaky effect, nor the bloom in the shadows, which we have heard alleged as being present in the first sample by the same maker.

From all we can learn, it appears that some slight specialities in treatment are required by the alabaster paper in order to secure the greatest success. Mr. Schering recommends the following formulæ:—

FORMULA FOR TREATING THE ALABASTER PAPER.

Silver Bath.

Nitrate of silver	80 to 85 grs.
Distilled water.	1 oz.

The bath must be rendered acid, so as to quickly reddens litmus paper.

Floated the paper for about five minutes after printing, until the shades become bronze coloured; wash in several waters, in the last of which put a little acetate of soda.

Toning Bath.

(Sufficient for six sheets.)

Chloride of gold.	15 grs.
Bi-carbonate of soda	150 grs.
Distilled water.	36 oz.

And it is advisable to add—

Citric acid	15 grs.; or,
Acetate of soda	1 oz.; or,
Phosphate of soda	1½ oz.

in order to get the desired tone.

Fixing Bath.

Hyposulphite of soda.	1 part.
Carbonate of soda	½ "
Water	8 "

We have not tried the formulæ given; but we should distrust the large amount of bi-carbonate of soda prescribed; a fifth part of it would be, in our estimation, nearer the mark.

COPYRIGHT IN ENGRAVINGS.

WE call the attention of photographers to a decision of the Court of Common Pleas, Lord Chief-Justice Erle, and Justices Willes, Byles, and Keating sitting in Banco, on Saturday last. The Copyright Acts relating to engravings give to the proprietors of such copyrights the sole right to reproduce or copy in any manner whatever the engravings protected by the provisions of the Act. The phraseology employed appears to us very comprehensive: it says distinctly that the engraving shall not, without permission of the owner of the copyright, be "engraved, etched, or worked in mezzotinto or chiaroscuro, or otherwise, or be in any other manner copied in whole or in part," &c. To common apprehension this phraseology would cover every possible mode of copying, photography not excepted. The law is said to be the perfection of reason; but certain acute lawyers have held that, as photography was an art unknown at the time when the Act was formed, and could not, therefore, be contemplated or comprehended by its provisions, and that therefore photographic reproductions were not copies within the meaning of the Act.

In a recent case, which we reported, a verdict—damages £10—was obtained by Mr. Gambart against a photographer for pirating the engraving of "The Horse Fair;" but a rule was obtained to set aside the verdict, on the ground to which we have just referred—that photographs were not contemplated by the Act, by virtue of which Mr. Gambart possessed his copyright. The hearing of the case took place on Saturday last, and we are glad to record that the decision of the Judges was to the effect that the law in this instance was in accordance with common sense and common honesty. Mr. Justice Erle referred to the very comprehensive words of the Act, which included, any manner of copying, and this applied, in his opinion, not only to the modes of copying then known, but to any other mode which the ingenuity of man or the progress of science should develop.

We are glad that this question has been brought to a decision, because we regard everything like dishonesty, meanness, or piracy, associated with any branch of our art or its professors, as degrading it, and all belonging to it, in the eyes of the public generally, and we trust that this decision will tend largely to put a stop to the illegal piracies which have so frequently been brought under public attention of late.

FORMIC ACID IN THE DEVELOPER.

[We have been favoured by Mr. Henry Claudet with the following copy of a letter addressed to the *Moniteur* in answer to Dr. Van Monckhoven's article on the use of Formic Acid in the Developer, which was reproduced recently in our pages.]

MY DEAR SIR,—The last number of the *Moniteur de la Photographie* contains the result of some experiments made by Dr. Van Monckhoven, which are not favourable to the employment of formic acid, as described in the process I indicated in the *Photographic Journal* of the 15th of July, 1862 (and in the *Photographic News* of July 18th), which was communicated to the Academy of Sciences by Mr. Balard subsequently.

Such a communication made by Dr. Van Monckhoven, who is considered as an authority in photography, will probably discourage many persons disposed to try a process which ought to contribute to the progress of instantaneous photography, generally regarded as the highest aim of all engaged in this art. I believe it to be my duty therefore to ask you to publish my reply to the conclusions of the photographic *savant* in question. Dr. Van Monckhoven says:—

"The negative developed with pyrogallic acid mixed with formic acid, appears quickly, but the formic acid does not retard the reduction of the silver, producing on the film a greyish deposit of silver."

This result shows me, that Dr. Van Monckhoven has used too much formic acid, or that his acid was too strong to be introduced in the formula in the proportion that I have indicated.

In fact, in the course of my experiments, I have also had the deposit of silver of which Dr. Van Monckhoven when the dose of formic acid has been too strong.

When the collodion plate has been withdrawn from the nitrate of silver bath, *decidedly acid with nitric acid*, and well drained before putting in the slide, then exposed it in the camera, and a solution of pyrogallic acid mixed with formic acid applied, the image appears instantly, giving a very vigorous negative; and, however far the development be pushed, there should be no reduction of metallic silver upon the plate.

It is necessary that the exposure in the camera should be five times less than if developed with pyrogallic acid and acetic acid; and half the time necessary where it is developed with the sulphate of iron; having moreover the advantage over the latter that there will be no necessity for intensifying. If this result be not obtained, the most probable cause will be that the formic acid has been too strong. This should not, of course, discourage the experimentalist, but simply induce him to continue changing the proportion of formic acid in the developer until he gets the results I have obtained daily for two years, and of which I am able to show the proof in the large photographs and the cartes de visite sent by my father to the exhibition of the "Palace of Industry," all of which have been done by my process.

Having had the occasion to operate before M. Balard in his last visit to London, this illustrious *savant* was so much surprised at the rapidity of photogenic action resulting from the new addition of formic acid in the developing bath, that he himself proposed to me to present the communication of my process to the Academy of Sciences, as a discovery capable of rendering service to photography.

I have frankly described the process with the desire of rendering it easy to all operators, and the formula that I have given succeeds with me perfectly. I recommend Dr. Van Monckhoven to make new experiments. I need not say to him that the state of the nitrate bath, more or less acid, the constitution of the collodion and of the pyrogallic acid that he used, and, perhaps, the quality of light under which he operated, may cause a modification in the proportions of formic acid necessary. He will, I think, be soon convinced that formic acid, added to the developer, is attended with the best results, as an accelerating agent, the most powerful in the formation of the photographic image.—Yours very truly,

HENRY CLAUDET.

Critical Notices.

THE FAITHFUL SHEPHERDESS: A Statue, by Miss S. D. DURANT. Photographed by STEPHEN THOMPSON. London: MARION & Co.

We unhesitatingly affirm our conviction, at the risk of the double charge of bad taste and want of gallantry, that the photography is here, in our view, better than the sculpture. The figure is one of a series of colossal statues executed for the Corporation of London, amongst which are some fine productions by good men. "The Faithful Shepherdess" is in illustration of Beaumont and Fletcher's lines, running thus:—

"Look and see
The ring thou gavest me, and about my wrist
The curious bracelet that thou thyself did twist
From these fair tresses. Know'st thou Amoret?"

The expression and pose of the statue—which may now be seen in the Royal Academy, where we examined it—illustrate the lines sufficiently well; the drapery is also graceful, but the general effect of face and figure is "sticky," poor, and hard. Miss Durant, who is, we believe, a pupil of the Baron Triguetti's, holds a good position in a certain school of sculpture, and it may be heresy to express our want of admiration for the work; but it is so. Mr. Thompson has chosen a view which gives the best rendering to the subject and produces a really fine picture (12 by 10), which Her Royal Highness the Crown Princess of Prussia—we like the term Princess Royal of England better—for whom the work was photographed, has not only expressed her gracious approval of, but given permission for its publication.

We have received some fine things Mr. Thompson has recently been executing in Warwickshire, which are not, however, ready for publication yet.

THE DOUBLE SULPHATE OF IRON AND AMMONIUM AS A DEVELOPER.

BY H. S. NOVERRE.

I HAVE been using the double sulphate of iron and ammonium for the last two months, and as its employment appears likely to become general, I send you the formulæ I have found most useful. The advantages I find it to possess over the protosulphate of iron are the absence of all tendency to deposit on the shadows, that a shorter exposure is required in the camera, that the crystals keep well, and that, provided the solution has not been kept long, it may be mixed with solution of nitrate of silver, without becoming turbid, for several minutes.

The following is my experience as regards the strength of the solution:—

Sulphate iron and ammonia	25 grs.
Acetic acid	15 mins.
Water	1 oz.
Alcohol	q. s.

The above is a convenient solution for general use for views and portraits well lighted, and it keeps well.

Sulphate iron and ammonia	35 grs.
Acetic acid	20 mins.
Water	1 oz.
Alcohol	q. s.

This solution I have found useful for subjects badly lighted and for interiors, but is too energetic for ordinary work. I enclose a carte de visite, the negative of which was developed with this solution; the image started out at once, and after applying the developer, and in about two minutes, was of sufficient density to require no further intensification. The exposure was two seconds, with Dallmeyer's No. 1 B lens, with the X stop, in the open air. I do not think, however, that the result is as satisfactory as if it had been developed with the first-named solution, and intensified afterwards with pyrogallic acid.

A stronger developer is made thus:—

Sulphate iron and ammonia	100 grs.
Acetic acid	30 mins.
Water	1 oz.
Alcohol	q. s.

It answers very well for instantaneous work; it develops clearly and evenly, and is at the same time quite under control. This is best used fresh, as it may then be kept on the plate several minutes if the picture does not appear at once.

The solutions of the double salt do not appear to keep any better than those of the protosulphate of iron, but the crystals keep exceedingly well. I have had some of the salt loosely wrapt in paper for about two months, which is as good as the day it was bought.

25, South Street, Park Lane.

THE NEW FIXING SALT.

BY DR. VAN MONCKHOVEN.

1st. Contrary to M. Meynier's assertion, we have found that the rhodanide of ammonium (sulphocyanide of ammonium) is a violent poison; less so, it is true, than cyanide of potassium; but it is dangerous, nevertheless, to lead the public into error on this point; therefore, we repeat this substance is a violent poison.

2nd. The rhodanide of ammonium decomposes in the air; it acts as a fixing agent in the same manner as the rhodanide of potassium, which is less poisonous, much more stable, and is prepared much easier.

3rd. The rhodanide of potassium fixes the proofs in the same manner as cyanide of potassium; that is, it communicates a disagreeable yellow tone to the proof, especially if on albumenized paper. [Dr. Van Monckhoven's experience is at variance with our own, in this respect. We have not met with any yellowness in the whites.—Ed. P. N.]

4th. We can, however, avoid in great measure this yellow tone by adding to the rhodanide a small quantity of chloride of gold, which colours the solution red.

5th. The rhodanide of potassium communicates a yellow tone to the proofs which the gold toning seems to cause to disappear, but in reality again becomes apparent when the positive is left to dry.

6th. In fact I prefer, until a more complete examination, the hyposulphite to the new salt, which possesses no real advantage, for it contains sulphur like the hyposulphite, and there is no evidence that it cannot abandon a portion and sulphurize the proof. Besides, nothing proves that it completely dissolves the albuminate of silver, for the experiments made by us in this direction have proved very discordant.—*Bulletin Belge de la Photographie.*

ON DEVELOPING WITH PYROGALLIC ACID.

BY M. L'ABBE LABORDE.

In a note which I had the honour of presenting to the Photographic Society (of Paris), on the proportion of the iodides, and the value of each, in photography, I remarked that the nitrate and the acetate of alumina favoured the action of the gallic and pyrogallie acids, to the degree that the latter could rival the ordinary solution of pyrogallie acid. These salts, strictly speaking, do not increase the reducing power of pyrogallie acid, but they singularly hasten its action; it is precisely to this particular circumstance, and to the reasons which may give it importance, that I now propose to call attention.

All the salts of alumina do not enjoy this property in the same degree: thus, the formiate of alumina added to the solution of pyrogallie acid, is no sooner poured upon the negative, than the picture appears with all its details; the action of the nitrate and acetate of alumina is less prompt; the sulphate acts still more slowly. In alum, the employment of which, has been recently explained by M. Martin, it is not the sulphate of potassa that acts, but only the sulphate of alumina. Being induced, for certain reasons, to select nitrate of alumina, I employed the following formula.

Water	300 parts
Nitrate of alumina	1.50 "
Pyrogallie acid	1 part

The nitrate of alumina must be very pure, free from iron especially, and dissolved in water. This salt often contains some insoluble nitrate, and has such great tenuity, that part of it passes through the filter; the liquid is poured a second time upon the same filter, the pores of which, obstructed by the sub-nitrate, have become so fine, that the liquid passes through perfectly transparent. This solution keeps well, but the pyrogallie acid must not be added to it too long in advance of use. To always have a freshly prepared solution, divide a gramme of pyrogallie acid into ten parts, and put each portion into a piece of paper. When it is desired to

make a normal picture, for example, put into a test glass 30 grammes of the solution of nitrate of alumina and one portion of the gramme of pyrogallie acid; it is well to add a few drops of alcohol in order to cause the solution to spread rapidly over the collodion film, without any defect of continuity on the impressed plate. The alcohol may be omitted with small plates, which are easily covered without this auxiliary, and thus the action of certain alcohols which slightly fog the image is avoided. The quantity of nitrate of alumina indicated above is an average proportion, and may be varied. It is often objected to sulphate of iron that its action is too rapid and brusque to be managed; and many eminent photographers prefer a slow and progressive development. But in presence of the admirable results obtained by sulphate of iron, we must modify this view. For we may ask if the valued qualities of sulphate of iron are not due to its rapidity of action. In a slow and progressive development, the operator feels more mastery over the picture; but if the picture obeys only to exceed the aim, and destroy the equilibrium which should exist between the different tones of the picture, then there is only an apparent advantage in being able to regulate its coming. We know also that in photography, the things which do themselves are always more perfect than those which depend upon the skill of the operator.

The advantages which I think may be attributed to the rapid action of the developer are, that the negatives possess more detail, and rarely give those absolute blacks in the picture which never exist in nature. I readily believe, that upon leaving the camera, not only the iodide of silver, but the nitrate itself, is modified—not the nitrate that runs freely from its surface, but that in contact with, and adherent to the iodine, and which, under the developing agent, concurs more powerfully to the reduction than ordinary nitrate of silver. The question is—is this nitrate modified under the influence of light because it forms with the iodide of silver, which it tends to dissolve, a more sensitive compound; or, because it is in contact with organic substances, as alcohol and collodion, which it slightly penetrates? It is difficult to say: there it is, and, as we all know, great care is required when the developer is poured over the exposed plate; if the liquid is poured on carelessly, the reduction fails in the spot where the liquid is first poured, and not merely because we thus drive away the ordinary nitrate of silver, for if we restore it, we never succeed in re-establishing the equilibrium between this portion and the remainder of the picture. The almost sudden slackening in the appearance of the picture after the first reduction, which has brought it out almost entirely, clearly proves that there is one favouring circumstance, at least, and that we can replace it only very imperfectly by renewing the dose of pyrogallie acid and nitrate of silver. From this we may understand, that a developing agent, the slowness of whose action manifests the strongest tints first, will never show the weaker under so favourable an influence, and that there will be a defect in equilibrium between the first and the last; while a developer more prompt in its action, bringing everything out at the same time, will show the action of the light more faithfully.

When a picture is developed and washed in the space of a few seconds, the developer has scarcely time to penetrate to the surface of the glass, the imperfections of which are less evident, and there is one chance the more of obtaining a good negative. In fact, I have often remarked upon certain plates, spots which obstinately appear after a long development, while they are scarcely apparant when the nitrate of alumina, united with pyrogallie acid, had permitted the development and washing of the picture within the space of a few seconds. I do not speak of the impurities left on the surface of the plate, and which always produce spots, because the collodion becomes impregnated by them, but of the substances which adhere strongly to the glass, and seem, from the difficulty of removing them, to combine with it.

All the salts of silver which I have tried in conjunction

with pyrogallie acid allowed me to dispense with the addition of any other acid, excepting the pyrogallate of alumina, which may be employed alone, and demands the usual dose of acetic acid.

If the sulphate of iron was always successful, I should dispense with preparing another developing agent as prompt in its action; but it very often fails in cases where the pyrogallie acid and nitrate of alumina may give very good negatives. If, for example, we employ a collodion simply iodized with iodide of cadmium, sensitized in a neutral nitrate bath, the sulphate of iron will almost always blacken the exposed film, while pyrogallie acid united with nitrate of alumina will supply all the elements of success.—*Bulletin de la Société Française de la Photographie.*

AUTHENTICATED FORMULÆ.

CONTRIBUTED BY FIRST-CLASS PHOTOGRAPHERS.*

WE are enabled, by the courtesy of several gentlemen, who are recognized by the photographic world as amongst the very ablest exponents of the art, to publish the formulæ by which they habitually work. In most cases these formulæ are simple enough, and are just the same as are generally used by others; but their publication possesses this advantage: where it conveys nothing new, it gives confirmation to what is; for the most valuable confirmation of the worth of any process, is the publication of successful pictures. It, moreover, confers a dictum we have often urged, that success is due to the man rather than the method. An intelligent application of a process is essential to good photography; and a thoughtful application of art principles is essential to a good picture. Ruskin observes, that "patience and sand paper will not make a picture," although they may give a smooth surface; and the most perfect formula will not yield an artistic photograph, except it be in the hands of an artist.

PORTRAITURE.

MR. T. R. WILLIAMS'S FORMULÆ.—The prints are exquisitely delicate, perfect, and brilliant. Tone warm, neutral tint. Mr. Williams prefers a 30-grain nitrate bath to a stronger solution. A good commercial nitrate of silver, purified with carbonate of soda, if necessary. A trace of nitric acid, generally less than a drop in a pint of solution.

A commercial bromo-iodized collodion. Frequently a mixture of that of different makers, not unusually Mawson and Rouch.

Developing solution, in summer:—

Protosulphate of iron	15 grains
Acetic acid (glacial)	15 minims
Water	1 ounce
Alcohol	quantum suff.

In winter:—

Protosulphate of iron	30 grains
Acetic acid (glacial)	15 minims
Water	1 ounce
Alcohol	quantum suff.

Fix in a dipping bath containing saturated solution of hyposulphite of soda, and wash very thoroughly.

Intensify after the negative is dry, with bichloride of mercury and iodide of potassium, as used by the late Mr. Laev. Sometimes, before drying, but after fixing, with pyro and silver.

In printing, with albumenized paper prepared with 10 grains of chloride of barium, use a silver bath, strength from 30 grains to 50 grains per ounce. With most commercial papers containing an unknown proportion of chloride, use an 80-grain silver bath, with a trace of nitric acid, and float one minute.

Print in diffused light, not much deeper than required in finished print. Wash and tone in acetate of soda and gold

* We reprint the above from the YEAR-BOOK OF PHOTOGRAPHY and PHOTOGRAPHIC NEWS ALMANAC for 1863, as meeting many questions which frequently reach us.

bath, usual formula, but made always a week in advance of its use. Never use twice. Fix in abundance of hypo, one part in six of water. From eighty to one hundred card pictures fixed in about two quarts of hypo, which is never used more than one day. Wash for four hours in constant changes of water, drain a few minutes, and wash a few minutes without leaving off, then dry without further soaking.

MESSRS. SOUTHWELL BROTHERS' FORMULÆ.—The prints are, perhaps, the most brilliant published, and very round, and finely modelled. Tone, rich, warm, sepia and bishe tints.

The silver bath contains 40 grains to the ounce, slightly acid, with nitric acid.

Collodion, a good commercial bromo-iodized; frequently Mawson's.

Developing Solution—

Protosulphate of iron	4 drachms
Glacial acetic acid	4 "
Water	16 ounces
Alcohol	1 ounce

Intensify before fixing with—

Pyrogallie acid	80 grains
Acetic acid	200 minims
Water	16 ounces

and a few drops of a fresh silver solution.

In printing use a good commercial albumenized paper. Excite in a 90-grain bath. Tone, and fix in a bath of hypo and gold, using great care, and wash well.

MR. H. P. ROBINSON'S FORMULÆ.—The prints are rich, round, delicate and vigorous. Tone, deep purple, brown, and warm neutral tints. The only card portraits specifically rewarded with a medal at the International Exhibition, and at the Exhibition of the Scottish Photographic Society.

Nitrate bath—

Pure recrystallized nitrate of silver	12 drachms
Water	20 ounces
Acetic acid	10 minims.

Collodion, a good commercial bromo-iodized sample; frequently Ponting's or Rouch's, and sometimes mixed.

Developing solution—

Protosulphate of iron	200 grains
Acetic acid	1 ounce
Water	20 ounces
Alcohol	2 "

Intensify before fixing with—

Pyrogallie acid	40 grains
Acetic acid	2 ounces
Water	20 "

and in a little fresh silver solution.

Print on good commercial albumenized paper excited on a 60-grain bath. Tone in a gold and acetate of soda bath, usual formula, made always a week or two in advance.

MR. Mc NAB'S FORMULÆ.—The prints are distinguished by especial brilliancy, with exquisitely deep and transparent shadows. The tones are rich purple browns.

The silver bath is prepared in the usual way, from recrystallized nitrate of silver, 35 grains to the ounce of water. If, on using it for the first time, it shows a tendency to fog, it is slightly acidified with nitric acid.

The collodion, made after Hardwich's formulæ, frequently mixed with commercial bromo-iodized samples.

Developing solution, 15 grains of iron to the ounce of water, when the light is good; but in cold weather, and weak indifferent light, it is increased to 20 grains. When intensity is lacking, use—

Iron	4 drachms
Acetate of soda	1 drachm
Water	17 ounces
Pyroligneous acid	2 "
Alcohol	1 ounce

The plates are developed and well washed, and put aside

in a rack to dry, until we find it convenient to clean them. When they are dry, a line of varnish is put round the edges to prevent the film from being removed in the following operations of cleaning and intensifying. The plates are wetted again, and fixed with cyanid of potassium.

Intensify according to the character of the picture. If the negatives are nearly dense enough, and but slight intensifying is required, pyrogallic acid, $1\frac{1}{2}$ grains to the ounce of water, and one or two drops of silver from a 30-grain solution. When the negatives are feeble they are treated to a weak solution of iodine, which is floated upon the plates for a short time; they are afterwards copiously washed previous to applying the pyro and silver.—At other times, intensify by pouring on a saturated solution of bichloride of mercury, until the film is of a grey colour, after which it is washed, and a solution of iodide of potassium, of one grain to the ounce of water, is applied until a greenish yellow tint is produced.

In *printing* use *Rive* paper for soft negatives, and *Saxe* paper for hard ones. The sensitizing bath contains 90 grains of silver to the ounce; the paper is floated upon it from three to five minutes, according to temperature. Tone with Maxwell Lyte's formula.

MR. MAYLAND'S FORMULE.—The prints very delicate and full of half tone, and, at the same time, exceedingly vigorous and round. Tone, a rich, warm neutral tint.

The *silver bath* is 35 grains to the ounce, and is very slightly acid, with nitric acid. *Collodion*, a good commercial bromo-iodized sample.

Developing solution—

Protosulphate of iron (in summer)	15 grains
Acetic acid	20 minims
Water	1 ounce.

The solution is better for being a few days old. In winter the iron is increased to 30 grains.

Intensify before fixing with—

Pyrogallic acid	1 grain
Acetic acid	40 minims
Water	2 ounces

with a few drops of 15-grain solution of silver. Fix with hypo.

In *printing*, good commercial albumenized paper; an 80-grain silver bath; two minutes floating and rapid drying. Tone with the gold and acetate of soda bath. Fix with hypo, one part in five, never used twice.

MR. HAWKE'S FORMULE.—The prints are delicate, brilliant, and very bold. The tone, rich purple brown.

The *silver bath*.—40 grains to the ounce, slightly acid with acetic acid.

Commercial bromo-iodized *collodion*, frequently mixed.

Developing solution.—

Protosulphate of iron	2 drachms
Glacial acetic acid	1 drachm
Water	1 ounce
Alcohol	<i>quant. suff.</i>

Intensify before fixing with pyrogallic acid two grains, citric acid one grain in an ounce of water and a few drops of silver.

In *printing*, use Sandford's thin *Saxe* albumenized paper, a strong silver bath, and acetate of soda and gold toning bath.

MR. PARKINSON'S FORMULE.—The prints are very brilliant and bold and finely modelled. The tones a rich, warm, intense black, with very warm, flesh-like half tints.

The *silver bath* has 30 grains to the ounce, always treated, when new, with oxide of silver, and then slightly acidified with nitric acid.

Commercial bromo-iodized *collodion*, often a mixture of Thomas's and Ramsden's, and for rapidity Rouch's, or a mixture of Thomas's negative and Mawson's positive.

Developing solution, a 20-grain iron solution with 20 minims of acetic acid and alcohol *quant. suff.*

Print on albumenized *Rive* paper excited on an 80-grain silver bath slightly acid with acetic acid. Tone with gold and chloride of lime, Ommeganck's formula.

LANDSCAPE AND INSTANTANEOUS PHOTOGRAPHY.

MR. VERNON HEATH'S FORMULE.—The prints exquisitely delicate, brilliant, with rich and perfect warm tones.

A 36-grain *silver bath* nearly neutral, or very slightly acid with nitric acid.

Collodion.—Thomas's bromo-iodized magnesian collodion.

Developing solution—

Protosulphate of iron	8 grains
Glacial acetic acid	20 minims
Water	1 ounce
Alcohol	<i>quant. suff.</i>

Intensify with pyro and silver before fixing.

Print in albumenized paper salted with chloride of barium; excite in strong silver bath; tone with gold and acetate of soda bath.

MR. BLANCHARD'S FORMULE.—The instantaneous pictures by this formulae are well known as exceedingly well detailed and brilliant.

The *silver bath* contains 40 grains of pure recrystallized nitrate to the ounce, neutral or with a very slight trace of nitric acid.

The *Collodion* contains a large proportion of bromide, and is prepared expressly for instantaneous photography.

Developing solution—

Protosulphate of iron	30 to 50 grains
Glacial acetic acid	20 minims
Water	1 ounce
Alcohol	<i>quant. suff.</i>

Intensify by different processes according to quality of image.

MR. ENGLAND'S FORMULE.—The perfect detail and delicacy of these instantaneous pictures are well known.

The *silver bath* contains 40 grains of pure nitrate to the ounce, and is worked neutral.

The *Collodion* contains 3 grains of iodide of ammonium, and 3 grains of bromide of cadmium to the ounce, and is sometimes mixed with commercial samples.

The *Developing solution*—

Protosulphate of iron	48 grains
Glacial acetic acid from	12 to 20 minims
Water	1 ounce
Alcohol	<i>quant. suff.</i>

Intensify before fixing with a two-grain solution of pyro, citric acid, and a little silver.

Print on albumenized paper prepared with 4 grains of chloride of barium, and 4 grains of chloride of ammonium to the ounce. Excite on a 60-grain silver bath; print very deep; fix in saturated solution of hypo, then tone in a solution of hypo and gold, both fixing and toning baths always used fresh.

Proceedings of Societies.

LONDON PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held on the evening of Tuesday, the 5th instant. Mr. Glaisher, F.R.S., in the chair.

The minutes of a previous meeting having been read and confirmed, Mr. J. Parsons was elected a member of the Society.

Mr. Richards exhibited and explained the photographic apparatus of M. Bertsch, consisting of a small "automatic" camera for producing small pictures, a stereoscopic camera, and a mezzotint or enlarging camera, for producing amplified proofs from the small negatives. He remarked that the end of

photography for the greatest number of artists and amateurs was to enable them to bring home from their travels souvenirs or subjects for study. Hitherto great difficulties had prevented many from profiting by this beautiful discovery. For, besides the volume and weight of the instruments and baggage required for photographic operations, and the difficulty of focussing and correcting the chemical focus, artists and connoisseurs had objected to photography, or rather to the instruments in use, that those instruments produced landscapes without foregrounds and distances, therefore the perspective was inaccurate, and nothing indicated the real scale. The truth of this objection had been mathematically proved in many reports, and especially in the excellent work by MM. Barreswill and Davanne on Photography. Struck by these defects, M. Bertsch, whose name enjoyed a great celebrity in science, had sought the means of correcting them, and he had so completely succeeded that his invention would, he thought, work a revolution in the photographic art. The instruments of M. Bertsch being made after the most exact laws of optics, formed a new and complete system; their precision was mathematical, and they gave, without focussing or correcting the chemical focus, landscapes most remarkable, as well for the bold clearness of the foregrounds as for the natural effect of perspective. The automatic camera was constructed with the double aim of reducing the baggage of the photographic traveller into a very small space, and of sparing him the trouble and difficulty of focussing. It was so constructed that the pictures it produced were perfectly clear from the foreground to an indefinite distance, and would bear enlarging to the extent of a yard square without losing any of the details. The apparatus complete, permitting to operate in open air by the wet process, was composed of a small case like that of a landscape painter, containing all that is required for working in the field. It served as a laboratory, and enabled the plates to be prepared on the spot. It contained the chemicals, the plates, and all the other things necessary. Of a camera obscura, also contained in the case, which produced pictures of all the objects from eight to ten yards, up to an infinite distance. And of a light trivet or tripod. Stereoscopic views were obtained on placing first the camera against one of the lateral sides of the little shelf, and then for the second picture the camera was removed to the other edge, the breadth of the shelf being adjusted to this end. As some amateurs had found the views of the automatic camera rather small, M. Bertsch had a double automatic camera constructed, so as to make at once the two pictures. The magnifying apparatus was distinguished from others hitherto employed not only by its smaller volume and weight, but by the results. It was screwed to a window-shutter facing the south. Being thus disposed, the mirror by the means of a parallactic movement was set so as to introduce the solar light by reflection into the axis of the lens. After this the diaphragm was put to the point where the rays cross, when the picture appeared in great brightness on the screen. The screen was moved forward or backward, according to the size the picture required. The focussing was effected by means of a pinion. Then applying a sheet of sensitized paper or a prepared plate, the picture was obtained. A distance of two yards gave an image one yard square. On a collodion plate the effect was instantaneous. On paper prepared by M. Bertsch an exposure from 15 to 20 seconds was quite sufficient.

Mr. RICHARD illustrated the mode of manipulation, and also called attention to a variety of small negatives and enlargements 14 inches square.

A conversation then arose as to the price of the automatic camera and equipment, which it appeared was £8 10s., and of the enlarging camera £17.

Mr. RICHARDS, in answer to a question, stated that the lens was single lens of short focus. It required no focussing, as all objects from ten yards distant to infinity were sharp.

Some conversation on this subject, which seemed to excite surprise, followed.*

Mr. ENGLAND then read a paper on the recovery of silver and gold from waste solutions and other residues. He exhibited

* As the statement referred to seemed to excite surprise, it may be well to explain a simple optical fact, which does not seem to be sufficiently well understood by photographers. The fact that all objects beyond a given distance to infinity are rendered in focus, does not arise from any peculiarity of M. Bertsch's lens, but is true of all lenses. The shorter the focus of the lens, however, the shorter the distance at which all objects to infinity will be in sufficient focus; and thus M. Bertsch's lens, having a very short focus, defines all objects within a moderate range, and thence beyond, indefinitely, without focussing.—Ed.

some fine ingots of pure silver, and some containing a percentage of gold, and also some silver again manufactured into nitrate.

Some conversation followed, in which Mr. England stated he had melted as much as 64 ounces of silver at one operation.

Mr. SEBASTIAN DAVIS asked if he used a Black's furnace.

Mr. ENGLAND said, "No;" with his own, built as described in his paper. A chimney of about 25 feet gave sufficient draught. The small Griffin's furnace he exhibited was heated by gas, and a small assay could be effected by it in about twenty minutes.

Mr. DAVIS asked what fuel he used with his own furnace. He asked, because he had had some difficulty with an Aikin's blast furnace with double action bellows. After half an hour's operations he did not get a sufficiently high temperature. He therefore wished to know what fuel Mr. England used.

Mr. ENGLAND used coke broken into pieces, about the size of an egg. He thought the best furnace was one built with a few fire-bricks, as he had described. He found 60 ounces might be reduced by keeping the pot filled up as its contents became less in bulk. He did not find any blast required, only the ordinary draft secured by having a 25-foot chimney.

Mr. DAVIS asked if he had used cyanide of potassium to assist in ready melting.

Mr. ENGLAND had tried it and found no advantage. He found the use of nitre the best to aid in getting rid of sulphur, which was sometimes very difficult to remove entirely. If any traces of it remained, the whole mass of metal would have a grey leaden colour from its presence, and it was then very difficult to dissolve it in the acid. If the sulphur were all removed the metal would be perfectly white. It would then dissolve readily, and any gold present would be obtained as a black powder, and the chloride obtained from it was in all respects as good as when made from the pure metal.

Mr. BROOKES asked Mr. England if he had understood him to say that the ashes from black silvered papers were of a light drab colour and turned darker in the light.

Mr. ENGLAND said that the paper to which he referred was much of it not exposed; he had not especially noticed the colour of the ashes, where all the paper was previously blackened. The especial peculiarity to which he had referred was the fact, that, after burning the paper the silver evidently remained in the form of a chloride, and had not in the course of burning been reduced to the metallic form, notwithstanding the state of fine subdivision in which it was subjected to heat.

Mr. HART said he had had a furnace made similar to a pipe-maker's furnace, standing upon a circular iron frame, about 3 feet high. It was covered at the top and had an outlet at the back. With a 10-inch black lead crucible, he had a space of an inch or two all round. In 25 minutes he could get a white heat, and reduce 8 or 10 ounces of silver in three quarters of an hour. It cost about 25s. and was very portable.

Mr. ENGLAND said ordinary Blenheim pots were the best; black lead was acted upon and quickly destroyed.

After a vote of thanks to Mr. England,

THE CHAIRMAN called attention to two very fine life-sized portrait busts, by M. Claudet, of Dr. Diamond, the secretary of the Society, and of M. Laurier the secretary of the French Society, produced from the negative in which those gentlemen formed a group. They were enlarged by means of the solar camera and were entirely untouched. They were both sharp round, soft, well modelled and brilliant, that of Dr. Diamond being an especially fine likeness.

THE CHAIRMAN also announced that it was probable the members would be called upon to attend an extra meeting, of which due notice would be given in the various journals, in order to hear Mr. Smith's account of the sun pictures at South Kensington. If it were a fact that sun pictures were taken 50 or 60 years before the supposed discovery of the art, it was most interesting to learn the fullest particulars.

THE CHAIRMAN said it might possibly be interesting to the meeting to hear a few remarks on his photographic experiments in a recent balloon ascent. He prepared some paper with chloride of ammonium and excited it with a 50-grain solution of ammoniacal nitrate of silver, and produced a sensitive paper which he knew gave uniform results under uniform circumstances. One-half of a sheet was left at the Observatory at Greenwich, the other he took with him. He left instructions that a portion of the paper was to be exposed for one minute, the first out of every five minutes in succession; while he would give some one minute out of every five, as opportunity might permit. Whilst they were below the clouds the results were

nearly the same, but above the clouds there was no discoloration at all in one minute. With a guide before his eyes, as a test for pure white, he could detect no change whatever, although the direct rays of the sun were upon the paper. The dew-point was below zero at the time; whether it was the dry state of the atmosphere, or what, he could not at present determine. He now only spoke to facts. One piece of paper which was exposed for half an hour was not so dark as several of the pieces had become at Greenwich in single minutes. He hoped to try it again and should be glad to receive hints from any one before the next ascent. His chief attention on the last occasion had been directed to the remarkable results he had obtained with the spectroscope. He had commenced with a fixed slit which showed the lines, from B to G, with the light from the sky; but when he got above the clouds the light from the blue sky gave him no spectrum at all; when he got the direct light from the sun, however, the lines were vivid and innumerable. He wished to try the experiment again, and so verify his observations. He might remark, that notwithstanding the non-actinic character of the light, the blue end of the spectrum appeared considerably longer.

A conversation on the causes of the want of actinism followed.

Mr. ENGLAND suggested that the temperature might affect the question. Placing white glass over sensitive paper would, by increasing the heat, make it print quicker.

The CHAIRMAN thought the difference in temperature was not sufficient to make much difference. It was probably more due to the absence of moisture.

Mr. P. LE NEVE FOSTER said a similar condition might be induced by the chloride of calcium preservative box.

Mr. ALLEN suggested that much was yet to be learned as to how far atmospheric conditions affected actinism. All photographers were aware that sometimes an apparently bright light was very slow, whilst a light which looked dull was very energetic. He thought experiments in a vacuum would help to elucidate the question.

Mr. DAVIS suggested trying experiments with iodide of silver, on dry plates, to ascertain if the same action had occurred with the latent image when developed, as with the apparent image of chloride of silver.

The CHAIRMAN said if there were an unlimited number of balloon ascents he might have time for this. He believed atmospheric conditions affected the question of actinic influence largely. He found it necessary on dry days to regulate the moisture in the Observatory to secure regular results in his photo-magnetic and other registrations.

After some further conversation the proceedings terminated.

PHOTOGRAPHIC PIRACY OF ENGRAVINGS.

(*Court of Common Pleas. Sittings in Banco. Before Lord Chief Justice ERLE, and Justices WILLES, BYLES, and KEATING, Saturday, May 2.*)

GAMBART V. BULL.

THIS was an action for pirating Rosa Bonheur's celebrated print of the "Horse Fair" by photographing copies of it for sale. For doing this the plaintiff brought his action and recovered a verdict with £10 damages. A rule having been obtained to set aside that verdict on the ground that the Copyright Acts did not contemplate or apply to photographic copies.

Mr. Collier, Q.C., Mr. Prentice, and Mr. Brandt showed cause against that rule; Mr. Coleridge, Q.C., and Mr. Rew appeared in support of it.

The CHIEF JUSTICE, in giving judgment, said, in this action the question had been raised whether a photographic copy of an engraving was an infringement of the rights given to the engraver by the statutes of George II. and George III., and he was of opinion that it was. The statutes that protected the rights of engravers began with the statute of the 8th of George II., cap. 13, which in its preamble recited that print-sellers and other persons had, without the consent of inventors and designers, taken the liberty of copying, engraving, and publishing base copies of such works, designs, and prints, to the great prejudice and detriment of the inventors, designers, and proprietors. The preamble, however, did not conclude the enacting words, which prohibited the copying of any engraving that the author of the engraving had invented, and it appeared

to him that that statute in its enacting part went much beyond lowering the estimation and character of an engraver by publishing a spurious article in his name. Engravings were made for money reward. The object of this enactment was to give to the engraver a money value for the product of his mind embodied in the steel engraving, prints from which could be multiplied and sold. Then came the statute of the 7th George III., cap. 23, which gave the same protection to engravers, and persons were thereby prohibited to engrave, print, publish, or import for sale any copy of an original engraving. The 17th George III., cap. 57, was the statute on which this action was founded, which was an Act "for more effectually securing the property of prints to inventors and engravers by enabling them to sue for and recover penalties in certain cases." This Act recited the statute of the 8th of George II. and of the 7th of George III., and then went on to recite that whereas the said Acts had not effectually answered the purpose for which they were made, and it was necessary for the encouragement of artists, and for securing to them the property of and in their works, and for the advancement and improvement of the aforesaid arts, that such further provisions should be made as thereinafter mentioned, enacted that "if any engraver, etcher, print-seller, or other person shall within the time limited by the aforesaid Acts, or either of them, engrave, etch, or work, or cause or procure to be engraved, etched, or worked in *mezzo tinto*, or *chiaro oscuro*, or otherwise, or in any other manner copy, in the whole or in part, by varying, adding to, or diminishing from the main design, or shall print, reprint, or import for sale, or cause or procure to be printed, reprinted, or imported for sale, or shall publish, sell, or otherwise dispose of, or cause or procure to be published, sold, or otherwise disposed of, any copy or copies of any historical print or prints, or any print or prints of any portrait, conversation, landscape, or architecture, map, chart, or plan, or any other print or prints whatsoever which hath or have been or shall be engraved, etched, drawn, or designed in any part of Great Britain without the express consent of the proprietor or proprietors thereof first had and obtained," then the proprietor of such print may bring an action for damages against the persons so offending. It seemed to him that that statute contained extremely wide words. It prohibited any person from engraving or in any other manner copying. The question was whether a photographer taking a photographic copy of a print had in a manner copied that print. In common language he had made a photographic copy of that print. These prints were of value; they gave pleasure; and the statute said to the designer and inventor, "You shall have a monopoly of selling that object of attraction as your reward." If that was the principle laid down by the statute, a photographic copy might represent exactly the same idea, and so diminish the sale of the engraver's print and his reward. He saw no reason why these general words should not apply to any mode of copying known at the time when the statute passed, or why they should not apply to any of the modes of copying which the ingenuity of mankind and the progress of science have from time to time brought forward. He felt bound to say that whether a photograph was of the same size, or very much diminished in size from the print which it copied, the statute applied. One of these photographs represented a French horse-fair, and horses in the highest enjoyment of animal life brought out for the fair. Though represented in a diminutive form, they gave the same kind of pleasure to the purchaser that the original did, and the photographic copies would be an interference with the sale of the print by the owner, and within the mischief that the statute was intended to prevent. The plaintiff was, therefore, entitled to recover.

The other learned Judges concurred in this judgment.
Rule discharged.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, May 6th, 1863.

M. F. Zucchi recommends the following method of preparing collodion, which yields a very uniform, colourless product, and dissolves very readily in the mixture of alcohol and ether.

Into an earthen vessel put 20 lbs. of ordinary sulphuric acid and 9 lbs. of nitrate of potassa reduced to a coarse powder. These two substances are stirred together with a wooden spatula. At the expiration of 10 minutes add to the mixture 1 lb. of cotton, previously reduced to tufts the size of the thumb. The cotton is allowed to remain until a sample washed, pressed, soaked in alcohol, then dried, dissolves completely in a mixture of 2 parts ether and 1 of alcohol. When the solution takes place readily, the cotton is removed from the mixture, and freely washed in water until the latter no longer reddens litmus. After separating the water, by pressing the cotton in a linen cloth, it is placed in alcohol, and left for four-and-twenty hours. The alcohol acquires a yellow colour, and the cotton becomes perfectly white. It suffices then to free it from the alcohol by pressure, and to dissolve it in a mixture of 2 parts of alcohol and 15 to 20 parts of doubly-rectified ether, to obtain a collodion of excellent quality.

M. Zuchs employs the best carded cotton. It always has a yellow tinge, but upon operating as above it becomes quite white.

Treating the cotton with soda is useless; the sulphuric acid and saltpetre of commerce are sufficiently pure for the preparation, and the quantities of nitrate necessary are, according to the author, less than those usually prescribed.

The time of immersing the cotton in the acid liquors is almost always indicated, but the temperature they ought to possess is frequently omitted.

In summer, 10 minutes suffices for its complete transformation into a soluble product; while in winter we must place the mixture in a *bain-marie* before introducing the cotton, in order to prevent the precipitation of the bisulphate of potassium, which thickens the bath. If hyponitric acid is given off, and this inconvenience cannot be obviated by plunging the cotton beneath the liquid, it suffices to add a fresh quantity of sulphuric acid to stop the production of the irritant fumes.

The transformation of the cotton is not so prompt but that there is time to make successive trials of the immersed cotton to ascertain its perfect solubility. The alcohol employed by the author was 90 degs. strength, and the specific gravity of the ether 0.730.

The subject of enlarging photographic portraits was discussed at a recent meeting of our Photographic Society. The president, M. Regnault, made the following remarks:—Whatever may be the degree of ardour and hope with which photographers view the ultimate and radical solution of this problem, they are unanimous as to its importance; for the question of enlarging, considered as a whole, and under the hypothesis of a definite success, involves and resolves the principal *desiderata* of the photographic art. We know that the inherent distortion of large pictures, obtained direct by means of lenses of large diameter, is what most seriously vitiates and disfigures the products of this art, and that this defect fatally tinges them all, more or less.

Upon this point science is, unhappily, affirmative; and in spite of all artifices, expedients, and formulæ, and of the ingenuity of opticians and mechanicians, it asserts that distortion, in large pictures, is an inadmissible original vice. On the other hand, it has already, as we believe, proved that the small pictures obtained with very small lenses of short focus secure a perfect proportionality of reproduction. It has, according to recent works, which appear to merit every confidence, ascertained and proved in a constant and exact manner the conditions of distance, amplification, and form, which it is necessary to combine, to arrive in some measure, at these results mechanically. This, then, is a prodigious stride to make in the matter of *enlarging*, the result of which depends, as we perceive, on the previous perfection of the *diminishing*. If, therefore, we can transform these little pictures in all their proportions in a quite satisfactory manner, photography will produce works of a value hitherto unknown, since they will combine the qualities due both to extreme rapidity of force and a total absence of distortion.

Now, in what regards the participation of optics with instruments generally, the optical enlarging of very small pictures by the negative or positive method seems to be in a state of most encouraging progress, if even this is not saying too little.

But a great difficulty has always obstinately opposed the efforts of operators, and is even inherent to the sensitive film that sustains the image. When we enlarge a small collodion picture, it happens that the intimate or superficial structure of the film is enlarged with the rest, and presents inequalities, streaks, and other impurities previously invisible, so that the enlarged image becomes corroded and coarse.

Albumen remains much more homogeneous and pure in aspect after enlarging. But, as every one knows, it possesses the defect of requiring much longer exposure, so that in employing it one of the two great advantages of the process in question is lost.

So that the qualities of albumen and collodion will be reciprocally reversed; with the one, long exposure and relative beauty of the image; with the other rapid exposure, but an imperfect image. We must, therefore, propose as an aim to inquirers, in this part of the question, either the appropriation of these two substances to the office of support of the enlarging, by means which are the *x* of the problem, or by the induction or discovery of a new substance which shall combine the qualities, hitherto isolated of the two first. Inventors will, besides, be quite free in their researches: they will be neither limited nor cheated by a narrow programme, that which will give the means of obtaining the most perfect images in enlarging will receive the prize offered, whatever those means may be; if, however, the maximum of success realized by it appears sufficient.

M. Bertsch remarked that experience had shown him, that albumen carefully prepared and free from dust, and spread uniformly on a glass plate, and, when the iodide of silver has not been dissolved by cyanide of potassium, but by hyposulphite of soda, presents no appearance of network, even when enlarged one hundred diameters. If we could but increase its rapidity, it would, doubtless, permit our reproducing of the natural size, a full length portrait of seven-tenths of an inch in height. In these conditions, there would be no appreciable trace of network or of distortion.

M. Ernest Lacan relates, in the *Moniteur de la Photographie*, an account of his visit, on the 13th ult., to M. Lewitsky, to experiment upon a box of dry collodion plates received from M. Liesegang. The hour was five in the afternoon. M. Lewitsky took a plate from the box, and placed it in the frame without even brushing the dust off. It was exposed 6 seconds, the lens being a Voightlander, 3 inches diameter. The negative was washed in water, and developed with sulphate of iron, made by the usual formula, and the picture appeared with all its details. A portion was, however, slightly fogged, the light having penetrated by a hole made in the box at the Custom-house. It was now a quarter past 5. Another plate was exposed 15 seconds, which was too long. The box had been sent by railway on the 15th of March; consequently, the plates had been prepared a month. Similar experiments, made previously by M. Lewitsky, gave identical results. It thus appears that, with these dry plates, we can operate in the same manner as with moist collodion, without prolonging the time of exposure, which is evidently a very important step in advance.

M. Mazac, who has studied dry collodion for a long time, states that he makes collodion plates retain their sensibility a long time by covering them with a solution which he calls *vegcto-animalisée*, and which differs from anything employed hitherto. He does not give the formula.

A new photographic journal has been established at Milan, entitled *La Camera Oscura*.

SPONTANEOUS DEVELOPMENT OF THE COLLODION IMAGE.

SIR,—I was yesterday engaged in making an enlarged

negative from a collodion transparency, and tried two plates with two and three minutes' exposure. The pictures were both deficient in half-tone, and I accordingly increased the length of time to six minutes for the next picture. I was surprised on taking the plates into the dark room, to find a faint impression of the image spontaneously developed; on pouring on the iron, it *immediately* thickened up with chalky lights, but did not fog in the shadows as I should have expected. I repeated the experiment with an exposure of twenty-five minutes, and obtained a similar result with a decided increase of intensity, as much indeed as is usually required for a collodion positive. I poured on a few drops of iron developer in three draughts of water, and slightly increased the intensity. On removing the iodide I found that the image was of a powerful orange colour by transmitted light and of a greenish tint by reflected light. I think it not improbable that with a longer exposure, and the sun shining through the transparency, a negative might be obtained without any development.

I mention the foregoing as I remember having read the report of a discussion on the same subject.—I am sir, yours very obediently,

JNO. TEMPLETON LUCAS.

3, St. John's Wood Road, Regent's Park, May 1st, 1863.

[An important element in forming an estimate of the cause of the phenomenon, is a knowledge of the process employed; if simply wet collodion, then with what the collodion is salted. A simply iodized collodion without organic matter present would not, we think, with any exposure give a visible image. Bromide of silver is, however, more like chloride of silver, and blackens visibly under the action of light.—Ed.]

PHOTOGRAPHY IN THE UNITED STATES.

DEAR SIR,—You have probably noticed that we in this country have gone crazy over the Harrison's globe lens. We brag of it, and our writers tell great things of it, say it will do anything up to—say 100°. I have examined much work done by many of these instruments, and have been disappointed. In purchasing one of these lenses, a person may be lucky enough to get one that comes up to promise, but in many instances they must be exchanged several times before a perfect one is found. The "six-inch focus" ones are advertised to cover a circle of light twelve inches in diameter. Generally this circle does not exceed eleven inches.* One man will boast that his six-inch lens almost covers an 8 by 10 plate, while another finds decided blurring in the corners of only a four-fourths plate when working the same priced and sized article. It is this uncertainty of working that will damage confidence in them: could it be avoided they would prove a great success. We have an eminent optician here who will shortly manufacture a lens having all the virtues of the "globe" at one-half the price. He is at present perfecting his patents, and very many operators are awaiting his instruments rather than pay the exorbitant prices of Harrison's.

Photographically speaking, there is no excitement here. The carte de visite fashion is changing. The old style of showing a full length figure stiffly braced against an impossible railing or column, or savagely holding fast of a chair back, is dropped, and the more artistic style of a simple vignette face is now in vogue.

Double printing has not yet been introduced among us, but from its more beautiful effects, will soon become fashionable; for, truly, the American taste, heretofore so neglected, is becoming much more refined. I enclose a card portrait by myself, double printed. My method is simply to print the face with an ordinary vignette block or glass, and then taking the paper out of the printing frame, and holding it

in the left hand, lay on it a piece of glass having an oval black paper pasted to the middle of it as a shield to the face. Expose to the sunshine a few seconds, keeping the shield glass constantly moving in a small circle over the face, holding it by the corner with the right hand. I omitted to say that the negative must be taken with a neutral background somewhat darker than the face. In this way the head seems to stand out in relief from an atmosphere of space behind, thus avoiding the disagreeable effect of a blank white paper.* Mr. Moran, of Philadelphia, has made some very fine moonlight pictures by double printing. He first prints the sky, making a full moon by laying a coin over the glass, and then prints from the negative. The effect of having a tree, branch, or chimney-top appear against the moon is very fine. His photographic etching of "The Haunted House," printed in this way, is exquisitely fine, and perhaps stands at the head of American Art Photography.

By the bye, these Philadelphians have a Photographical Society which effectually surpasses our ancient institution in New York. They make theirs a sociable club, have rooms open at all times,—have a Photographic Library, walls full of pictures, floor full of easy-chairs, and all that sort of thing. They certainly beat us, but an old adage says, "A new broom sweeps clean." Will it last?—Very respectfully yours,

F. F. THOMPSON.

PHOTOGRAPHY AND MURDER.

DEAR SIR,—On the 15th instant, after reading an account of the murder of the young woman, Emma Jackson, in Stt Giles's, I addressed a letter to Detective-officer James F. Thomson, informing him that "if the eyes of a murdered person be photographed within a certain time after death, upon the retina will be found depicted the last thing that appeared before them, and that in the present case the features of the murderer would most probably be found thereon." I exemplified my statement by the fact of my having, four years ago, taken a negative of the eye of a calf a few hours after death, and upon a microscopic examination of the same I found depicted thereon the lines of the pavement on the slaughter-house floor. This negative is unfortunately broken, and the pieces lost.

I enclose you Mr. Thomson's reply, together with his permission for me to make any use I please of it.

The subject is of too great importance and interest to be passed heedlessly by, because if the fact were known through the length and breadth of the land, it would, in my estimation, tend materially to decrease that most horrible of all crimes—*Murder*.—I am, dear sir, yours very truly,

WM. H. WARNER, *Photographer*.

Metropolitan Police Office, Scotland Yard, S. W.

Friday, 9 P.M., 17th April, 1863.

RE "MURDER IN ST. GILES'S."

SIR,—I hasten to acknowledge the receipt of your letter of the 15th inst., handed me about an hour since.

The secret you convey in your letter—photographing the eyes of a murdered person—is one of the greatest importance, but, unfortunately it is unavailing in this instance, for various reasons, three of which I will give you:—1st. Life had been extinct some 40 hours prior to my seeing the body of Emma Jackson. 2nd. The eyes were closed. 3rd. A post mortem examination has been made, and she has been buried—shell coffin—since Monday last.

In conversing with an eminent oculist some four years ago upon this subject, I learned that unless the eyes were photographed within 24 hours after death, no result would be obtained, the object transfixed thereon vanishing in the same manner as undeveloped negative photograph exposed to light. I did not, therefore, resort to this expedient.

* The six-inch focus refers, of course, to the focus from the back lens, and probably means eight or nine inches equivalent focus. We have a Dallmeyer's No. 1 triple, with an equivalent focus of a fraction under eight inches, which covers a circle of light twelve inches in diameter. It is a pity that the misleading system of speaking of the focus of compound lenses, as measured from the back glass, is not abandoned, both here and in the States.—Ed.

* The specimen received from Mr. Thompson is very effective.—Ed.
† This arrangement is something similar to that attempted by the Photographic Society of London, some years ago, but which was found too expensive and not sufficiently appreciated to be continued. It is certainly a desirable arrangement, and we shall be glad to learn that it is successful in the City of Brotherly Love.—Ed.

With my sincere thanks for your kind letter and information,
I am, sir, faithfully yours,
W. H. WARNER, Esq.
Literary Institute, Ross, Herefordshire.

JAMES S. THOMSON.
Sup. Detective.

*Metropolitan Police Office, Scotland Yard, S.W.
Tuesday, 21st April, 1863.*

SIR,—In reply to your note of yesterday, I can only say that you have my compliance to make any use you please of my previous letter to you.—I am sir, in haste, faithfully yours,

W. H. WARNER, Esq. *Officer of Detective Police.*
Literary Institute, Ross, Herefordshire.

The International Exhibition.

REPORT OF THE JURY ON PHOTOGRAPHY AND PHOTOGRAPHIC APPARATUS.

Continued from p. 167.

Most satisfactory illustrations of the advancement of the art are shown in the display of instantaneous photographs, stereoscopic and otherwise.

In the production of marine subjects—sea, shipping, clouds, and atmospheric effect, it seems as if little remained to be accomplished, as the pictures of G. W. Wilson, Blanchard, and of C. Breese (United Kingdom, 3049) exemplify. The exquisite transparent stereographs contributed by the latter gentleman possess photographic and artistic beauties quite unsurpassed; every drop of water in breaking waves or foaming cataracts is reproduced by an operation perfectly instantaneous and with a transparency beyond comparison. The sea-gull is arrested on the wing, the balloon depicted in its ascent, whilst foreground and distance, sea and cloud, are each at the same time perfectly rendered. The effects of sunset and moonlight are beautifully given; and to add wonder to beauty, images of objects photographed by the light of the moon alone are amongst his contributions. It may be interesting to state in connection with these pictures that, instantaneous as they manifestly are, no other contrivance but a cap held in the hand was used for covering and uncovering the Dallmeyer's lens, thus showing the rapidity of the motion of the human hand, and the simple way of overcoming what has been thought so difficult a matter.

The street scenes of Mr. England (United Kingdom, 3117), executed for the London Stereoscopic Company, are perfect and beautiful, especially those of his views in Paris.

As not inferior to the majority of the contributions of this kind must be mentioned the instantaneous pictures of Warnod of Havre (France, 1548). They are of a size larger than the majority of instantaneous productions, consisting of sea, cloud, and shipping, possessing a delicacy and vigour with perfect definition in the highest degree satisfactory.

Reproduction is another interesting and valuable branch of the art which has attained a very high state of perfection, some excellent illustrations of which are exhibited.

The magnificent copies of the cartoons of Raphael, produced respectively by a member of the Jury and Mr. Caldesi (United Kingdom, 3061), cannot well be overrated. Mr. Caldesi's copies of the Phidian marbles rank amongst the most valuable applications of the photographic art.

Mr. Downes's map (United Kingdom, 3068) and other reproductions of engraving are perfect. The enlargements of Mr. Warner (United Kingdom, 3176) are most excellent.

The obtaining of fixed natural colours by means of photography still remains, as was before remarked, to be accomplished; but the Jurors have pleasure in recording that some very striking results of experiments in this direction were forwarded for their inspection by a veteran in photographic research and discovery, M. Niepce de St. Victor. These, about a dozen in number, 3, by 2½ inches, consisted of reproductions of prints of figures with parti-coloured draperies. Each tint in the pictures exhibited, they were assured, was a faithful reproduction of the original. Amongst the colours were blues, yellows, reds, greens, &c., all very vivid. Some of the tints gradually faded and disappeared in the light whilst under examination, and a few remained permanent for some hours. The possibility of producing natural colour thus established is a fact most interesting and important, and too much praise cannot be awarded to the skillful research which has been to this extent crowned with success. The Jury record their obligations to their chairman, Baron Gros, to whose personal solicitation they were enabled to obtain a sight of these remarkable pictures.

We now approach, for very brief notice, a variety of contributions illustrating several very important applications of photography. First amongst these may be mentioned the photo-lithographic process of Mr. Osborne, the photo-zincographic process of Col. Sir H. James, the photographic process of Mr. Fox Talbot, the processes of Mr. Paul Pretsch for producing, by the combined aid of photography and electricity, plates for printing, either in intaglio or relief. In all these the impression is produced in printer's ink, and by the aid of the ordinary letter-press, lithographic, or copper-plate presses; all the facility for rapid reproduction of the prints, and all the permanency, or, indeed, as far as the impression is concerned, the indestructibility of ordinary prints or engravings are in the productions under notice secured. Mr. Osborne (Victoria, 385) exhibits specimens by his process of the official colonial maps and plans of Victoria. All these are for the purposes required faultless, and consist of reproductions of the original plans, &c., in the same size and on amplified and reduced scale, any proportion to the original being, of course, easily obtained and with perfect accuracy. For such purposes his process has attained its utmost limit of perfection. The productions of Col. Sir H. James (United Kingdom, 3101), of a similar character, and applied to similar purposes, are not less perfect. The specimens exhibited consist of copies of the Ordnance maps, Hozarth's engravings, a page of an early edition of Shakespeare, Prynne's Horace, &c., also specimens of the transfers of the zinc plates, &c., illustrating different stages of the process. In a process based upon the same principle, and styled by Col. James phototypography, the sheet of paper is made to serve the purpose of the plate of zinc or lithographic stone, and where a small number of impressions only is required answers every purpose, as the speci-

mens contributed show. The specimens of Mr. Paul Pretsch (United Kingdom, 3140), both of block printing and intaglio printing, are very interesting, and in many instances exceedingly fine. We may mention as especially worthy of notice a print of the Venus of Milo and the portrait of a child, engraved by this process, and printed by means of the copper-plate press. These plates have received a little aid from the burin of the engraver, and render exceedingly satisfactory pictorial effect. The specimens of Mr. Fox Talbot's (United Kingdom, 3167) photographic process are very interesting; but his method has not received that practical attention by which results of high pictorial excellence has been attained. Mr. Ramage, of Edinburgh (United Kingdom, 3143) contributes some of the most perfect specimens of litho-photography in the Exhibition, consisting of the reproduction of engravings. The process by which they are produced is not stated, but is understood to consist in a modification of the processes of other discoverers. MM. Poitevin (France, 1503), Leimercier (France, 1501), and some others in the French court, also exhibit fine specimens of photo-lithography.

Based upon a similar principle, but of less economic importance, are the various carbon processes. The specimens produced in this country have not yet attained a degree of excellence, which renders them of much practical value. The most perfect process of which any specimens are exhibited are those by the method of Mr. Joubert (United Kingdom, 3105), styled the prototype process. Some of these are very good, and the rate of production is stated to be very rapid, but the details of the method are not made public. In the French department, specimens of very high excellence are exhibited. Amongst the contributors here, first, is the honoured name of Poitevin, to whose research much of what has followed is due. MM. Fargier, Garnier, and Salmon, Charavet and Carmarsac, and others also exhibit carbon prints of much excellence, a detailed notice of which, however, would occupy too much space here. M. Leth, and some others in the Austrian department, also exhibit very fine carbon prints.

The exhibitors of photographs in enamel, or vitrifiable colour, are not numerous, but many of the specimens are very fine. Mr. Joubert exhibits in the British department a number of large pictures enamelled on plates of glass, some of which are in monochrome, and others in a variety of tints, and are produced in some instances from negatives direct from nature, and in others consist of reproductions of engravings. A very high degree of excellence is obtained in many of them, and it is probable that an extensive application of the process for decorative purposes will ere long be made. M. Lafon de Carmarsac (France, 1506) exhibits some very charming photographic enamels, the application of which is in a different direction to those of Mr. Joubert. M. Carmarsac's specimens chiefly consist of miniature portraits. It is impossible to overrate the delicacy and perfection of many of these examples.

The application of photography to textile materials is very interesting, although its objects have yet to be developed. Madame Lafon exhibits some charming specimens on white silk, in which the photography and the designs possess much merit. In the Italian department some similar specimens were added after the conclusion of the Jurors' labours.

The applications of photography to the progress of astronomical science are not so numerous in the present Exhibition as the interest and importance of the subject might have rendered desirable. Mr. Warren De La Rue (United Kingdom, 2893), exhibits a series of his valuable photographs, recording the various phases of the total eclipse of the sun of 1860, which were produced in Spain in conjunction with the expedition sent out expressly for observing and recording the various phenomena in connection with that event. Several important points which up to that period were of considerable uncertainty and debate, were effectually and indisputably established by the aid of these photographs, and which, without their evidence, must still have remained undecided. Mr. De La Rue also exhibits his photographs of spots on the sun and of the moon in various phases. Mr. Beckley (United Kingdom, 3009), also exhibits a series of photographs of much interest, showing the spots on the sun at various periods.

The application of photography to the production of the enlarged images of the microscope receives many valuable illustrations, the exhibitors of which can, however, only be briefly chronicled here. Mr. Reeves Traer (United Kingdom, 3171) and Mr. Olley (United Kingdom, 3132) exhibit prints on paper from large negatives of minute objects taken through the microscope. M. Lackerbauer (France, 1553) exhibits some exceedingly fine enlarged microscopic images as transparencies on glass. M. Roncalli (Italy, 1249) exhibits some fine enlarged images on paper. In addition to these some interesting specimens are shown in which the inverse result is produced. These consist of reduced copies of pictures for microscopic examination; the results, although partaking of the character of toys, may yet become of important application. Mr. Reeves (United Kingdom, 3144), Mr. Stovin (United Kingdom, 3163), and M. Dagron (France, 1543), exhibit interesting specimens in this class.

In reference to the productions of many of the colonies, the Jurors have not space to enter into detailed notice; they may mention, however, that in many instances in their awards of merit to colonial exhibitors they felt that recognition of the circumstances under which the contributions were produced was necessary, and that a less amount of excellence here was worthy of mention than would have sufficed to secure it where the facilities for good results were more accessible.

The Jurors, in terminating their report, cannot conclude without stating their conviction that, rapid and important as the progress of photography has been since the Exhibition of 1851, it affords promise of still wider development, and still more important results, both in the stations it already occupies and in others it is yet destined to fill. Much of the progress already attained has been due to the disinterested exertions and research of individuals, but they may add their conviction that still more may be attributed to the influence of the Photographic Society. This Society, founded under the august auspices of the late lamented Prince Consort, who to the perfol of his death continued its patron, and took the deepest interest in its welfare, and the minor associations of a similar character which have since sprung up, have, by concentrating and fostering the exertions of individuals, contributed in a degree not easily calculated to the present high position of the art. The exhibitions of the Photographic Society, held from year to year, have been at once the incentives to exertion and the landmarks of progress; during the past, and will, doubtless, continue to exercise a still more marked influence on the future; and the Jurors of the next International Exhibition will, probably, be called upon to chronicle results to which those now recorded bear but a small proportion in beauty, vastness, and importance.

HUGH WELCH DIAMOND, Reporter.

Talk in the Studio.

INSENSITIVE PATCHES ON RESINIZED PAPER.—Mr. Burgess, of Norwich, writing on the occurrence he had met with of insensitive mottled patches on resinized paper, says:—"It seems to me that the paper becomes *hardened* by keeping after being resinized, so much so, that when it has been kept a month or two, a 60-grain bath will no longer penetrate it sufficiently to combine with the chloride, except the little that happens to be in the surface. The paper does not repel the solution as though it were greasy, the surface being completely *wetted*, and yet when dry and exposed to the light, it is found that very little chloride of silver has been formed. I have not tried the addition of alcohol, having found an efficient remedy by increasing the strength of the bath to 80 grains per ounce. If the *hardening* of the paper does really take place, I think it a very valuable property, rendering a print on resinized paper much more permanent than one on albumenized or plain paper."

TINTING ALBUMENIZED PRINTS.—We have a hint to offer as to the method of applying the dye or tint to albumenized prints as described in our pages a few weeks ago. Instead of immersing the wet print, let it be dried first, and then float on the tinting solution the same as exciting on the silver bath. A cleaner, better effect is produced, possessing more delicacy. We have received from Messrs. Bailey and Son some of Mr. Sutton's photographic tints which may be applied as we have described. These possess some advantages in variety and colour over those before described, and will answer the purpose admirably.

CALCIO-CHLORIDE OF GOLD, &c.—We have recently been trying Mr. Sutton's calcio-chloride of gold as prepared by Messrs. Bailey and Son, of Wolverhampton. It answers capitally; toning rapidly to any tint without giving the slightest trouble. As it is sent out in solution only requiring diluting prior to use, it will especially answer the purpose of many amateurs who desire to decrease their preparatory labours as much as possible. The only hint we would give in opposition to the instructions on the bottle would be to dilute considerably more than is recommended. With the proportion of water recommended to be added, namely, from 3 to 5 times the bulk, the toning is almost too rapid.

INSTANTANEOUS PORTRAITURE FOR CHILDREN.—Mr. Inskip, of Scarborough, has sent us a pretty portrait of a laughing child, evidently taken instantaneously. He has also sent us details of his mode of working in such case. The collodion is made with four grains of soluble cotton, made as described in our ALMANAC dissolved in equal portions of ether and alcohol, the latter having a specific gravity of .820. It is salted with three grains of iodide of ammonium and three grains of bromide of cadmium. The silver bath contains 35 grains to the ounce, neutralized with a few drops of a saturated solution of carbonate of soda. If it should fog a little, glacial acetic acid is added until it works clear. The child is arranged on a table, brought out as much to the light as possible. All blinds are thrown back to get all the light possible without direct sunlight. A Barr's short focus lens is used without stops, and the exposure is as short a time as possibly can be given—not time to count one. The picture is developed with 25 grains of iron to the ounce, with 6 drachms of acetic acid, and 6 drachms of methylated spirit to 20 ounces. After developing the picture well out it is washed, fixed, rewashed, and dried. The picture generally is rather thin with the short exposure. The edges are varnished to keep on the film. After moistening the plate with water, a solution of iodide of potassium and iodine in water, about the colour of sherry, is applied, the plate is well washed again and re-developed with pyrogallic acid 2 grains, citric acid 1 grain to the ounce, with a few drops of a 20-grain solution of silver, until the required density is obtained. Mr. Inskip adds:—"I have no doubt but some will think it too tedious a process to use, but I find it to my advantage to take the extra trouble, and have no doubt others would do the same."

To Correspondents.

R. C. R. B., Jeenseewalway.—The use of a collodion containing a good body of pyroxylene will aid you in obtaining density, and the use of a cadmium iodizer, and about 14 grains or more of a bromide will aid in preventing the red solarization to which you refer. 2. Pinholes arising from printing ten or a dozen copies of a varnished negative can only arise from the use of an imperfect varnish. A good spirit varnish would protect the film better. 3. The prints being cold when finished arises from over-toning. If you used, as you say, a large amount of citric acid in clearing your

bath, you have probably weakened it considerably by the free precipitation of silver; it would, moreover, liberate nitric acid, and this would make the prints look cold and poor. 4. There are no special instructions required for copying engravings. Use a copying camera; stop your lens down as much as the light will permit, so as to secure definition; use a strong and acid nitrate bath; a collodion giving sufficient density; or bearing continued intensification without leaving the plate. If sufficient intensity is not easily obtained, proceed as follows: apply bichloride of mercury, wash, apply a one-grain solution of iodide of potassium, wash, and apply a strong solution of pyrogallic acid and silver. In copying oil-paintings more care is required in getting suitable lighting, and the use of a freely bromized collodion. 5. Pin-holes in tannin plates most probably arise from turbidity in some of the solutions. Transparencies of tannin plates are produced by exposing them under a negative for a few seconds, and developing in the ordinary manner.

G. H. C.—Acetate of soda may be used in combination with carbonate of lime; and the latter may be added in excess without doing harm. We cannot, with certainty, say how long the bath so prepared will keep. That must be ascertained by trial. If your toning bath bleaches too much, make it weaker or keep it longer before you use it, or place it in an open vessel for some time before use. A dark spot in the centre of the negative is not a common occurrence with a single lens. Send us an example.

L. L. H.—We have had similar complaints of the same lenses by which your specimen was taken. Those regarding which you inquire, cover well, and are very rapid, and in all respects well suited to your purpose.

R. C. H.—Your cards have some good qualities, and their faults lean to the best side, that is softness rather than hardness. You have a little excess of diffused or front light, which detracts from perfect modelling, and your lens does not cover sufficiently well. Dr. Diamond's address is Twickenham House, Twickenham.

XXX.—We have repeated until we are weary of doing so, that the use of bicarbonate of soda in the toning bath is undesirable, except in skilled hands. You use 30 grains of bicarbonate of soda to half a grain of gold, and are surprised that the solution does not keep! We fear you have paid but little attention to the numerous articles on toning which have appeared in our pages. Read the instructions on this subject in our ALMANAC, or use the gold and acetate bath.

A. BISSIER.—When you speak of "a camera for 30s.," do you mean a camera and lens? If so, you cannot get anything worth having at the price. If you mean a camera only, it is quite possible to have a useful article for that money. If you want the cheapest portrait camera and lens, you may find in various catalogues quarter-plate French lenses at about 25s. or 30s., and camera to match at 14s. or 16s. Such a camera and lens will answer for a beginner.

J. BERGESS.—It is very probable that your suggestion as to the hardening of the resin may be correct. An enlarging camera to enlarge a quarter-plate negative to 18 by 15, with a lens of 9½ inches equivalent focus, should have a total length of between 60 and 70 inches, say, to avoid fractions, 60 inches on one side of the lens and 12 inches on the other, that is, between a lens and the negative. We should use less front light, and avoid the use of white lace draperies in the card portraits.

G. F.—It is quite true that the use of tartaric acid in the developer was tried years ago. We tried it ourselves six or eight years ago. But it is frequently wise to try old suggestions in the light of additional experience. It was proposed before for use with pyrogallic acid, now with sulphate of iron. The saccharo-sulphate forms fine crystals, which keep well. The old ethereal collodion, containing five parts of ether to three of alcohol, is rarely used now. At one time seven parts of ether to one of alcohol was commonly used. Equal parts of each are now generally employed, and in some cases two parts of alcohol to one part of ether.

F. C.—Use blotting paper at the corners of your dark slides; this will prevent the stains of which you complain. 2. In the case to which you refer the use of a turbid iron developing solution would cause pin-holes in the film.

PANORAMIC PICTURES.—We received a few weeks ago a panoramic picture about 13½ inches by 5½ inches, consisting of two halves joined together without any note or advice concerning it. We shall be glad to hear from the sender.

FRED. CLIFF.—Any gold remaining in used-out toning baths may be thrown down in the form of a dark powder by adding protosulphate of iron to the solution. This powder, which is metallic gold, may be converted into chloride of gold by means of aqua regia in the usual manner. Any silver in your developing solutions will be precipitated in the form of a grey powder, by allowing the solution to stand.

J. STIRIA.—If you found the addition of acid to the bath partially removed the markings, probably the addition of more will entirely remove them. You may add nitric acid freely to a bath in which a bromo-iodized collodion is used without appreciably diminishing its sensitiveness.

A. B. C.—The object of adding acetate of soda to the silver bath is to form acetate of silver, which, under certain circumstances, is favourable to density. We do not use it ourselves, nor recommend it; although it has some good authorities in its favour. 2. Reducing the size of the stop will increase both the extent of the definition and the depth of focus. Removing the stop further from a single lens will decrease the field covered, but improve the definition; putting the stop closer to the lens will increase the field, but injure the quality of definition. We do not know of any advantage the aplanatic possesses over the ordinary simple combination. Several correspondents in our next.

RECOVERY OF WASTE SILVER.

On another page will be found an interesting paper by Mr. England on recovery of silver from the various residues accumulating in photography. When it is remembered that little more than one and a half per cent. of the silver used in printing is actually to be found in the finished print, and that consequently upwards of £4 18s. 0d. out of every £5 spent in silver, is waste, unless some steps be taken to recover it, the question becomes one of serious import.

There will be of course a practical limit to the amount of silver possible to be recovered, and perhaps before that is reached, a limit to the amount it will be remunerative to recover, for it is quite possible in such operations for the cost of the effort to exceed the value of the result. But it is quite clear that with moderate effort a large proportion of the silver now wasted in too many establishments might be saved. Where the amount of work, especially of printing, is small, the trouble of recovering the silver as chloride and sulphide, and then of reducing it to a metallic state, seems somewhat formidable, and the result is scarcely considered worth the constant attention necessary. It is to be regretted that a system of collecting argentiferous waste, in which photographers might have confidence, is not established. Attempts have been made to establish such a system, we know; but, we believe, without much success. In other trades in which the precious metals are used the sweepings of the rooms, the dusters employed, &c., are regularly collected, and command a specific price remunerative to those who save and those who collect, and it is much to be regretted that a similar system does not obtain for photographers.

Refiners are prepared, we are aware, to purchase the various residues containing silver, or to reduce it, making a specific charge for the operation. But there is a want of confidence existing which makes photographers indifferent about availing themselves of the aid of the refiner. One photographer, we know, who took a large quantity of chloride of silver for reduction, was coolly informed, on calling again for the reduced metal, that the crucible had unfortunately cracked, and his silver was lost. It was not until after he had threatened legal proceedings he obtained any satisfaction; and, finally, he received a small ingot of metal, not a third of the legitimate yield of the chloride he had taken.

Mr. England informed us that a short time ago, after burning an accumulation of sensitive papers, he carefully weighed out three parcels of the ashes, each weighing two pounds, having well stirred and mixed the ashes first, to avoid any possible difference in their character. One parcel of two pounds he sent to one refiner for reduction; a second parcel was sent to another refiner, and the third he reduced himself. The result was—eight ounces of metallic silver from the first refiner; nine ounces from the second; and ten ounces and a half from the parcel he reduced himself. Thus, if the silver were worth only five shillings an ounce, he was mulct, in one instance, of twelve shillings and six-

pence; and, in another, of seven shillings and sixpence, in addition to the legitimate charge for reduction. We do not wish to imply that dishonesty is an invariable, or even a common characteristic of refiners, we should be sorry to entertain such a notion; but the fact is, that a few such cases destroy confidence, either in the men employed, or the method adopted.

Where it can be done, however, it is a very simple operation for the photographer to reduce his own residues. Where gas is available, and a moderate amount only of the metal has to be reduced, the small Griffin's furnace, heated by gas, Mr. England informs us, answers admirably. There are similar small furnaces, costing but a few shillings, made for burning coke. We have seen a small stove, in which coke was burnt, used successfully for the reduction; and it is possible, although difficult, to obtain sufficient heat in a kitchen fire. The London pots, recommended by Mr. England, are cheap and excellent, and the flux employed is also cheap.

In Mr. England's establishment, which we recently visited, the recovery of the waste silver is provided for in all the arrangements. In the sensitizing room the excited sheets are suspended on pins along two sides of the room, and beneath, to catch the droppings, are curved glasses placed at an incline so as to flow to a common point where a jar is placed. These curved glasses are each about two feet long, and are formed of parts of a cylinder of fourteen inches diameter which is cut into three sections. A cocoa-nut matting covers the floor, which, when worn out, will be burnt, and yield probably more than its original cost, in argentiferous ashes. Pieces of waste blotting-paper or rag are at hand to wipe up small portions of spilled silver solutions. The kaolin is made to give up its silver and is used over and over again. The silver in washing waters is precipitated as chloride, and in old hypo baths as sulphide. All clippings of sensitive paper and waste prints are burnt, and even the ashes of waste fixed prints are made to yield something. We do not know whether Mr. England has made any exact calculation of the saving effected; but we believe it is possible to recover from sixty to seventy per cent. of the silver used. This, even in small establishments, is, we think, worth saving.

FORMIC ACID IN THE DEVELOPER.

BY H. G. COOPER, JUN.

I HAVE lately been making many experiments with formic acid in the developer; and as the subject of its use is now attracting considerable attention, the results which I have obtained may not be uninteresting to your readers.

I took a nitrate of silver bath of the strength of 30 grains of pure fused nitrate to the ounce, and having made it perfectly neutral, added one drop of strong nitric acid to 20 ounces of it.

The collodions I employed in my experiments were all, with one exception, bromo-iodized.

As I am more partial to the use of iron as a developer than to pyrogallie acid, I determined to use the former for my experiments. I made a solution of pure sulphate of iron, 20 grains to the ounce, and added thereto varying quantities of acetic and formic acids. (The former glacial and the latter of the pharmacopoeal strength.) The proportions that I found to answer best were 10 minims of acetic and 15 minims of formic acid to the ounce of developer.

The results showed that with the above quantities the exposure was reduced to one-third (from fifteen to five seconds, for instance). The negatives developed exceedingly clean, without the least trace of any deposit on the shadows; but were all very much wanting in intensity, the image being thin and grey. I could only intensify it in the following manner: after fixing, wash well. If the collodion be at all likely to slip, the plate should be dried, the edges varnished, and it should then be soaked for some minutes in warm water. Have ready a filtered 2-grain solution of bi-chloride of mercury. Cover the negative with a good quantity of it, or, better still, immerse the plate in a dish full of the solution. Carefully watch it, and as soon as the dark tint which it at first assumes begins to turn lighter, rapidly wash it.

Now immerse it in a very weak solution of iodine in iodide of potassium or of ammonium, about 1 grain in 5 ounces of water. Should stains occur under the after treatment these two solutions have most likely been too strong. The remedy is simple,—use them weaker. Do not let the plate remain long in the iodide solution; no visible change will take place. After again washing it may be exposed for an instant to diffused daylight. All the operations must be performed in the dark room, as the result is then much more under control.

The negative is now to be re-developed with pyro and silver in the usual way. The image will then be found to be of a deep orange tint, and very delicate; the particles of silver composing it appearing to be very fine. If citric acid, in place of acetic, be added freely to the pyro solution, the image will be of a splendid purple, but, of course, is not so non-actinic as the orange tint.

I have not yet tried formic acid with the double sulphate of iron and ammonia, but recommend it to the attention of those whose object is to secure instantaneous results.

5, Aberdeen Park.

ENAMELLED PHOTOGRAPHIC PAPER.

BY L. M. LIESH.

As enamelled paper is now attracting attention, it may be of service to those interested in the matter to know that the same paper may be had in London, equal, if not superior, to any I have seen by the German makers. Some four years ago I experimented largely upon various enamelled papers, with the view of applying them to photographic printing—a short description of my experience in this direction may be interesting and useful to your readers, who may wish to experiment in a similar direction.

My object in making these experiments was two-fold, viz.: to get rid of the grain of the paper, and of the brown tone usual in albumenized prints.

After trying various enamels I found that the oxide of zinc was the only one answering the purpose. I applied to Messrs. De la Rue and Co., Bunhill Row, London, to prepare a quantity of paper and cards enamelled with the pure oxide of zinc. The greater portion of this paper was prepared with two coats of zinc white, some had three coats; and some only one coat; the cards had three coats, a portion of the paper had ten grains of chloride of sodium to the ounce of enamel. This I used to float on a new bath; after a sheet or so had been floated, the plain unsalted gave the best results. The paper was floated one minute on a 60-grain nitrate bath, and was dried and exposed under the negative in the usual

way. It printed in about half the time of albumenized paper, of a blue-black tone, which did not alter in the toning and fixing bath of hypo and gold I then used.

The details of the negative were rendered in the most exquisite manner, and when removed from the fixing bath nothing could be more beautiful. The drawbacks of the paper were that the prints were apt to become injured in the subsequent washing, and even after they were mounted they were easily scratched. I tried coating the enamelled paper with albumen, but the tone was not so good. As a whole I obtained the best results with the enamelled cards; those had three coats of enamel, which gave a beautiful surface. These cards were floated on the silver bath in the usual manner, and printed upon, with a mask of thin black paper put round the outside of the negative to confine the image within proper bounds and leave the necessary white margin round the card. This saved the trouble of mounting, and obviated any fear of cracking, as the cards remained quite flat, and the finished card presented a neater appearance than if the picture had been mounted on it.

I may here remark that the paper prepared for me by De la Rue and Co. was not liable to crack. It was beautifully finished, and if my memory serves me right, the price of the two-coat enamel was about £2 10s. or £3 per ream, deny. They would not make me a smaller quantity to order; but, I dare say, now it may be had in smaller quantities.

I had also some prepared by another London house, with certain modifications, such as introducing salt, &c., &c., but I did not obtain any advantage; the enamelling was not quite so well done as that by De la Rue.

The above experiments may induce some of your readers who may have more time, to devote their attention to the subject; and if it does no other good, it will tend to remove the monopoly or secrecy that at present exists respecting the enamel paper.

Grange Road, Darlington.

LANDSCAPE AND INSTANTANEOUS PHOTOGRAPHY.

BY W. H. WARNER.

It may prove interesting to some of your readers to know of a formula which at all times will give satisfactory results whether employed as an instantaneous process or otherwise. It is one that I have used for every kind of work during the last eighteen months; it is certain, sure, and safe; it keeps well, and, above all, it is economical. To many of the veterans in photography it is probably well known already, but it is for the benefit of those gentlemen who have only occasional opportunities of practising our beautiful art, but who, nevertheless, appreciate a good negative, and are all the more pleased when they get one, I address myself.

Collodion.

Ponting's plain iodized 5 oz.
Perry's (new) bromo-iodized 10 oz.

mixed, it will keep any length of time, and works equally well at seven years old as it does at one month.

Bath.

Any good commercial sample of nitrate of silver 40 grains to the oz. made according to Lake Price's formula.

Developer.

Proto-sulphate of iron 30 grs.
Water 1 oz.
Glacial acetic acid, crystallizable at 50° 30 mins.
Nitric acid 1 min. to every 4 oz. of solution.
Alcohol quantum suff.

When the subject is well out, wash thoroughly. The nitric acid makes the film close and tough; it never reticulates in the hottest weather.

Fixing Solution.

Cyanide	10 grs.
Water	1 oz.
Nitrate silver	1 gr.
Wash thoroughly.	If not sufficiently dense, use—			
Iodine resublimed	$\frac{3}{4}$ gr.
Iodide potassium	1 "
Citric acid	1 "
Water	1 oz.

Be sure and not make up this solution with alcohol, as it causes stains on the plate.

My friend, Mr. Blanchard, in a late article, states that he has found that by the use of the iodine the negatives become hard. They do so *without the citric acid*, but I have printed fully 2,000 prints from one negative, intensified with my formula, and the last was equally as good in tone as the first. The addition of the nitric acid is also important, the plate works foggy and dirty without it—with it, clean and brilliant—the difference would be found at once. It also enables the iron solution to be kept for a long time without deteriorating.

Wash well and use

Pyro...	1 $\frac{1}{2}$ grs. (hot weather)
	2 to 3	"	(cold weather)
Citric acid	1 $\frac{1}{2}$ "
Water	1 oz.

Add 2 drops of a 20-grain solution of silver, *not* from the bath. Keep this moving on the plate until the solution becomes of a pale sherry colour, or rather, to the inexperienced operator, until the points of light appear sparkling and brilliant. Then *well wash*.

It must be apparent to every one that citric acid in this formula is brought prominently forward; for many years it has been my constant habit of using it. I found when using the collodions of Bolton and Co., Thomas, and Perry (Sheffield), that it gave me brilliant and beautiful negatives when others who used acetic acid failed. Mr. Keene, of Leamington, recommends acetic and citric acids mixed in the pyro solution; this gives very excellent results, but it occasions a little extra washing; it however rather tends to keep the positive soft and harmonious.

In conclusion, should any of your readers be tempted, in the course of the summer, to visit Ross and the lovely scenery of the Wye, I shall be happy to see them and help them out of any difficulties they may get into, photographic of course.

Scientific Gossip.

SPECTRUM analysis, after having passed through the preliminary stages of wonder and implicit credence, has now arrived at that point at which people begin to throw doubts upon the absolute accuracy of its deductions. It has been lately discovered that the spectrum of an element is not always identical in its different compounds; lines which are absent in one compound being rendered apparent by the presence of another body, and strong definite lines, hitherto considered to be characteristic of an element, being altogether effaced when some other body is present. M. Mitscherlich has remarked that the spectrum given by chloride of barium in presence of an excess of hydrochloric acid, is quite different to the spectrum of barium itself. At first he was inclined to attribute this fact to the presence of another metal, and in order to satisfy himself on this point he examined it synthetically. The arrangements adopted were very simple; the solutions to be examined were placed in a glass tube, closed at the upper end, and having the other drawn to a point and bent nearly to a right angle. The liquid flowed slowly through a bundle of fine platinum wires lodged in the point, and allowing at the same time the re-entry of air into the tube. He usually added a salt of ammonia to the solutions to facilitate the volatilisation of

the dissolved salt. In studying the chloride of barium spectrum he filled one of these tubes with a solution of acetate of baryta, with the addition of acetate of ammonia, and he filled another tube with concentrated hydrochloric acid. Upon placing the extremity of the first tube in a flame he found it produced rays characteristic of barium. When this was removed, and the tube containing hydrochloric acid was placed in the flame, no lines whatever were produced; but on placing the bundles of platinum wires at the extremity of these two tubes simultaneously in the flame, he saw the spectrum which he had previously obtained with chloride of barium. M. Mitscherlich has noticed analogous facts with the chlorides of calcium and strontium: but upon experimenting with iodides, fluorides, and sulphides of the alkaline earths, similar results were not obtained, the spectra observed being those characteristics of the metals themselves. Copper gave curious results in its different combinations; the chlorides and iodides of copper give distinct spectra according to the combination. Sulphide of copper gives no spectrum; this fact might be attributed to the fixity of this combination, but the following experiment puts this explanation out of the question:—A solution of chloride of potassium, in presence of sal-ammoniac and excess of hydrochloric acid gives no spectrum in spite of the volatility of chloride of potassium, whilst this salt by itself, and much more diluted, gives the characteristic ray of potassium. This may be accounted for by the reduction of the salt being in the latter instance effected by the flame, which in the first instance could not be the case.

It is important to note the fact that certain rays in the spectrum of a metal may be effaced by the presence of a different substance in the flame: thus, the blue ray of chloride of strontium disappears in presence of the spectrum produced by chloride of copper with addition of sal-ammoniac.
